

Xmas 1902

To my dear Father : —

Wishing you a very Merry
Xmas & a Happy New Year with many
more to follow.

This book was purchased with part of the
money of the "Sutton Scholarship". A
prize which I won solely by your early
advice & teaching, & by your never failing
kindnesses.

From your affectionate, &
grateful son

Austin C. LeRoussignol

PREFACE

IN preparing the new edition of this Dictionary my object has been to produce a book which shall serve as a reliable and readily available work of reference for the Practitioner and Student of Medicine.

The general scheme of the book—so skilfully planned by the late Sir Richard Quain and his assistant editors—has been preserved, and the special emphasis laid on the diagnosis and treatment of disease has been maintained, although the pathology and ætiology have also been very carefully considered and revised. Some departure from the original plan has been deemed advisable. Many articles—excellent in themselves but not in accord with the special object in view—have been omitted, while repetitions have been as far as possible excluded. It has thus been found practicable to include a large number of new articles, to rewrite many others, and yet to publish the Dictionary in a single volume. The recent and ever-increasing incursions of Surgery into the realm of Medicine have received adequate recognition, and more space has been allotted to what are generally known as ‘special branches.’ A large number of cross references have been inserted in order to bring under the notice of the reader articles giving further information on the various subjects.

My sincere thanks are in the first place due to the Contributors, without whose labour and hearty co-operation it would have been impossible to have produced this work in the short period of eighteen months. For the readiness with which they received suggestions, for the self-suppression with which they permitted deletions, and for the rapidity with which they completed their articles I can hardly be sufficiently grateful. For the pathological and more strictly scientific articles I have secured the co-operation of those in touch with experimental work, and have throughout freely availed myself of the services of the younger members of the profession.

To Dr. Harold and Dr. Bosanquet, the Assistant Editors, my obligation is greater than I can easily express. Without them the task could never have been performed; and my principal regret is that the readers of this work can have no conception of the untiring labour which they have bestowed upon it.

The enterprise and courtesy of the Publishers deserve hearty editorial recognition. They have enabled us to insert twenty-one full-page plates (fourteen of them in colour), and have transformed my own task into a delight.

For the information of readers it should be stated that in articles for which two contributors are jointly responsible the names are, where possible, placed side by side, but that when the article written by one contributor has been revised by another the name of the reviser is placed under that of the original contributor.

H. MONTAGUE MURRAY.

LIST OF PLATES

PLATE		
I. BACTERIA	<i>facing page</i>	123
II. MORBID APPEARANCES OF THE BLOOD	156
III. CEREBRAL ABSCESS AND CEREBRAL HÆMORRHAGE	174
IV. TUMOURS OF EPITHELIAL TYPE	244
V., VI. MALARIAL PARASITES	950
VII. OPHTHALMOSCOPIC APPEARANCES	1122
VIII. OPHTHALMOSCOPIC APPEARANCES	1124
IX. PACHYMEMINGITIS HÆMORRHAGICA AND GENERAL PARALYSIS	576
X., XIII. PAINFUL AREAS IN VISCERAL DISEASE	1138
XIV. PAINFUL AREAS IN VISCERAL DISEASE	1140
XV., XVI. REGIONAL ANATOMY OF THE TRUNK	1242
XVII. SPECTRA OF PIGMENTS	1510
XVIII. SECTIONS OF THE SPINAL CORD	1520
XIX. TUMOURS OF CONNECTIVE-TISSUE TYPE	1760
XX., XXI. URINARY DEPOSITS	1798

LIST OF CONTRIBUTORS

- ABERCROMBIE, JOHN, M.D., F.R.C.P., Physician to, and Joint-Lecturer on Medicine at, Charing Cross Hospital; Consulting Physician to the Foundling Hospital.
- ADAMI, J. G., M.A., M.D., Professor of Pathology at McGill University, Montreal.
- ALLBUTT, T. CLIFFORD, M.A., M.D., LL.D., F.R.S., Regius Professor of Physic in the University of Cambridge; Consulting Physician to the Leeds General Infirmary.
- ALLCHIN, WILLIAM H., M.D., F.R.C.P., F.R.S.E., Physician to the Westminster Hospital.
- ANDREW, The late JAMES, M.D., Physician to, and Joint-Lecturer on Physic at, St. Bartholomew's Hospital.
- ANDREWES, F. W., M.A., M.D., B.Ch., F.R.C.P., D.P.H., Lecturer on Pathology at St. Bartholomew's Hospital, and the London School of Medicine for Women.
- BALL, JAMES BARRY, M.D., Physician to the Department for Diseases of the Throat, Nose, and Ear, at the West London Hospital.
- BALLANTYNE, J. W., M.D., F.R.S.E., F.R.C.P. Edin., Assistant Physician to the Royal Maternity Hospital, Edinburgh; Lecturer on Antenatal Pathology at the University of Edinburgh.
- BANKS, SIR JOHN, K.C.B., M.D., D.Sc., LL.D., Regius Professor of Physic in the University of Dublin.
- BARKER, ARTHUR E., F.R.C.S., F.R.C.S.I., Surgeon to University College Hospital; Professor of Surgery at University College, London.
- BARON, BARCLAY J., M.B., C.M., Physician for the Diseases of the Throat and Nose to the Bristol General Hospital.
- BASTIAN, H. CHARLTON, M.A., M.D., F.R.S., F.L.S., Consulting Physician to University College Hospital; Emeritus Professor of Medicine at University College; Physician to the National Hospital for the Paralysed and Epileptic.
- BATTEN, FREDERICK E., M.A., M.D., F.R.C.P., Assistant Physician to the Hospital for Sick Children, Great Ormond Street.
- BÄUMLER, C. G. H., M.D., Professor of Clinical Medicine and Director of the Medical Clinic at the University of Freiburg-im-Breisgau.
- BEACH, FLETCHER, M.B., F.R.C.P., late Medical Superintendent of the Darenth Asylum.
- BECK, The late MARCUS, M.B., M.S., Surgeon to University College Hospital, and Professor of Surgery at University College, London.
- BEDDOE, JOHN, B.A., M.D., F.R.S., late Physician to the Bristol Royal Infirmary.
- BEEVOR, CHARLES EDWARD, M.D., F.R.C.P., Physician to the National Hospital for the Paralysed and Epileptic; Physician to the Great Northern Central Hospital.
- BENNET, The late J. HENRY, M.D., Physician-Accoucheur to the Royal Free Hospital.
- BINZ, CARL, M.D., Professor of Pharmacology in the University of Bonn.
- BIRKETT, JOHN, F.R.C.S., Consulting Surgeon to Guy's Hospital.
- BLACKER, GEORGE F., M.D., F.R.C.S., Obstetric Physician to University College Hospital, and to the Great Northern Central Hospital.
- BLANDFORD, GEORGE F., M.A., M.D., F.R.C.P., Lecturer on Psychological Medicine at St. George's Hospital.
- BLAND-SUTTON, JOHN, F.R.C.S., Assistant Surgeon to the Middlesex Hospital; Surgeon to the Chelsea Hospital for Women.

- BOLTON, J. S., B.Sc., M.D., B.S., Assistant Pathologist to the London County Council Laboratory, Claybury.
- BOND, CHARLES JOHN, F.R.C.S., Surgeon to the Leicester Infirmary.
- BOSANQUET, W. CECIL, M.A., M.D., M.R.C.P., Physician to Out-patients and Pathologist to the Victoria Hospital for Children; Medical Registrar and Pathologist to Charing Cross Hospital.
- BOWLBY, ANTHONY A., C.M.G., F.R.C.S., Assistant Surgeon to, and Surgeon-in-Charge of the Throat Department at, St. Bartholomew's Hospital.
- BOWLES, R. LEAMON, M.D., F.R.C.P., Consulting Physician to the Folkestone Hospital.
- BOYD, FLORENCE NIGHTINGALE, M.D., Surgeon to the New Hospital for Women.
- BOYD, STANLEY, M.B., B.S., F.R.C.S., Surgeon to, and Lecturer on Surgery at, Charing Cross Hospital; Surgeon to the Hospital for Consumption and Diseases of the Chest, Brompton.
- BRADFORD, JOHN ROSE, D.Sc., M.D., F.R.C.P., F.R.S., Physician to University College Hospital; Professor-Superintendent of the Brown Institution; Professor of Materia Medica and Therapeutics at University College, London.
- BRADSHAW, T. R., B.A., M.D., M.R.C.P., Assistant Physician to the Liverpool Royal Infirmary.
- BRAINE, C. CARTER, F.R.C.S., Senior Anæsthetist and Lecturer on Anæsthetics at Charing Cross Hospital.
- BRANTHWAITE, ROBERT WELSH, M.D., D.P.H., H.M. Inspector under the Inebriates Act.
- BRISTOWE, The late J. SYER, M.D., LL.D., F.R.S., Consulting Physician to St. Thomas's Hospital.
- BROADBENT, J. F. HARPIN, M.A., M.D., late Medical Registrar at St. Mary's Hospital.
- BROADBENT, SIR WILLIAM H., Bart., K.C.V.O., M.D., LL.D., F.R.C.P., F.R.S., Physician-in-Ordinary to H.M. the King; Consulting Physician to St. Mary's Hospital, and to the London Fever Hospital.
- BRUCE, ALEXANDER, M.A., M.D., F.R.C.P., F.R.S.E., Assistant Physician to the Royal Infirmary, Edinburgh; Lecturer on Neurology to the Edinburgh School of Medicine.
- BRUCE, DAVID, M.B., C.M., Lieut.-Colonel R.A.M.C.
- BRUCE, J. MITCHELL, M.A., M.D., LL.D., F.R.C.P., Physician to Charing Cross Hospital; Consulting Physician to the Hospital for Consumption and Diseases of the Chest, Brompton.
- BRUCE, WILLIAM, M.A., M.D., LL.D., Surgeon to the Ross Memorial Hospital, Dingwall.
- BRUNTON, SIR T. LAUDER, M.D., LL.D., D.Sc., F.R.C.P., F.R.S., Physician to St. Bartholomew's Hospital.
- BUCHANAN, The late SIR GEORGE, B.A., LL.D., M.D., F.R.S., Medical Officer of H.M. Local Government Board.
- BUCHANAN, W. J., B.A., M.B., B.Ch., Major I.M.S.
- BULLOCH, WILLIAM, M.D., Lecturer on Bacteriology and General Pathology at the London Hospital.
- BULSTRODE, H. TIMBRELL, M.A., M.D., D.P.H., Medical Inspector to H.M. Local Government Board, and Lecturer on Hygiene at Charing Cross Hospital.
- BUTLIN, H. TRENTHAM, D.C.L., F.R.C.S., Surgeon to St. Bartholomew's Hospital.
- BUZZARD, THOMAS, M.D., F.R.C.P., Physician to the National Hospital for the Paralysed and Epileptic.
- CADGE, WILLIAM, F.R.C.S., Consulting Surgeon to the Norfolk and Norwich Hospital.
- CAIGER, F. FOORD, M.D., F.R.C.P., Medical Superintendent to the South Western Fever Hospital, Stockwell.
- CANTLIE, JAMES, M.A., M.B., C.M., F.R.C.S., Surgeon to the Seamen's Hospital, Greenwich; Lecturer on Applied Anatomy at Charing Cross Hospital.
- CARR, J. WALTER, M.D., F.R.C.S., F.R.C.P., Physician to the Royal Free Hospital, and to the Victoria Hospital for Children; Joint Lecturer on Medicine at the London School of Medicine for Women.
- CARTER, R. BRUDENELL, F.R.C.S., Consulting Ophthalmic Surgeon to St. George's Hospital, and to the National Hospital for the Paralysed and Epileptic.
- CASSON, WILLIAM A., Barrister-at-Law, Auditor to the Local Government Board.
- CAYLEY, WILLIAM, M.D., F.R.C.P., Consulting Physician to the Middlesex Hospital, and to the London Fever Hospital.
- CLARKE, J. MICHELL, M.A., M.D., F.R.C.P., Physician to the Bristol General Hospital, Professor of Pathology at University College, Bristol.

- CLOUSTON, THOMAS SMITH, M.D., F.R.C.P. Edin., Physician-Superintendent of the Royal Asylum, Morningside, Edinburgh; Lecturer on Mental Diseases at the University of Edinburgh.
- CLOVER, The late J. T., Lecturer on Anæsthetics at University College Hospital.
- COBBOLD, C. SPENCER, M.D., F.R.C.P. Edin., late Medical Superintendent of the Asylum for Idiots, Earlswood.
- COLEY, WILLIAM B., M.D., Surgeon to the New York Cancer Hospital; Clinical Lecturer on Surgery in the Columbia University.
- COLLIER, JAMES STANSFIELD, B.Sc., M.D., Registrar to the National Hospital for the Paralysed and Epileptic.
- COOPER, ARTHUR, Surgeon to the Westminster General Dispensary.
- CRAIG, MAURICE, M.A., M.D., Assistant Physician at the Bethlem and Bridewell Royal Hospitals.
- CRAWFURD, RAYMOND H. P., M.A., M.D., F.R.C.P., Assistant Physician to King's College Hospital, and to the Royal Free Hospital.
- CROCKER, H. RADCLIFFE, M.D., B.S., F.R.C.P., Physician to the Skin Department at University College Hospital.
- CURLING, The late T. B., F.R.S., Consulting Surgeon to the London Hospital.
- CURNOW, JOHN, M.D., F.R.C.P., Physician to King's College Hospital; Professor of Clinical Medicine in King's College.
- CURRIE, ANDREW STARK, M.D., late Assistant to the Professor of Physiology in the University of Glasgow.
- DALBY, SIR WILLIAM B., B.A., M.B., F.R.C.S., Consulting Aural Surgeon to St. George's Hospital.
- DANIEL, P. L., F.R.C.S., Assistant Surgeon to the Metropolitan Hospital; Surgical Registrar to, and Demonstrator of Practical Surgery at, Charing Cross Hospital.
- DAVIDSON, ALEXANDER, M.A., M.D., F.R.C.P., Consulting Physician to the Royal Infirmary, Liverpool, and Emeritus Professor of Pathology in University College, Liverpool.
- DAVIDSON, JAMES MACKENZIE, M.B., C.M., Medical Officer in charge of the Röntgen-Ray Department at Charing Cross Hospital, and at the Royal London Ophthalmic Hospital.
- DEAN, GEORGE, M.A., M.B., C.M., Bacteriologist to the Antitoxin Department at the Jenner Institute of Preventive Medicine.
- DEAN, HENRY PERCY, B.Sc., M.S., F.R.C.S., Surgeon to the London Hospital; Consulting Surgeon to the North-Eastern Hospital for Children; Teacher of Operative Surgery at the London Hospital.
- DELÉPINE, SHERIDAN, B.Sc., M.B., C.M., Professor of Pathology, and Director of the Pathological and Bacteriological Laboratory, at the Victoria University, Manchester.
- DORAN, ALBAN, F.R.C.S., Surgeon to the Samaritan Free Hospital for Women and Children.
- DRESCHFELD, JULIUS, M.D., B.Sc., F.R.C.P., Physician to the Manchester Royal Infirmary; Professor of Medicine at Owens College, Manchester.
- DUNCAN, ANDREW, M.D., B.Sc., F.R.C.P., Physician to the Seamen's Hospital, Greenwich.
- DUNCAN, The late J. MATTHEWS, M.A., M.D., LL.D., F.R.S.E., Physician-Accoucheur to St. Bartholomew's Hospital.
- DURHAM, The late ARTHUR E., F.R.C.S., Surgeon to Guy's Hospital.
- DURHAM, HERBERT E., M.A., M.B., B.C., F.R.C.S.
- EDEN, T. W., M.D., C.M., Assistant Obstetric Physician to, and Lecturer on Practical Midwifery at, Charing Cross Hospital; Physician to Out-patients at the Chelsea Hospital for Women.
- EDGECOMBE, WILFRID, M.D., F.R.C.S., Harrogate.
- EDWARDS, F. SWINFORD, F.R.C.S., Surgeon to the West London Hospital, and to St. Peter's Hospital.
- EYRE, JOHN, M.D., M.S., D.P.H., F.R.S.E., F.R.M.S., Bacteriologist and Lecturer on Bacteriology at Charing Cross Hospital.
- FARQUHARSON, ROBERT, M.D., LL.D., M.P., formerly Lecturer on Materia Medica at St. Mary's Hospital.
- FAYRER, SIR JOSEPH, Bart., K.C.S.I., M.D., LL.D., F.R.C.P., F.R.C.S., F.R.S., F.R.G.S., F.R.Z.S., Physician-in-Ordinary to H.M. the King; late President of the Medical Board, India Office; Consulting Physician to Charing Cross Hospital.
- FENWICK, SAMUEL, M.D., F.R.C.P., Physician to the London Hospital.

- FERRIER, DAVID, M.A., M.D., F.R.C.P., LL.D., F.R.S., Professor of Neuropathology in King's College ; Physician to King's College Hospital ; Physician to the National Hospital for the Paralysed and Epileptic.
- FINNY, J. MAGEE, B.A., M.D., F.R.C.P.I., King's Professor of Medicine at the School of Physic in Ireland ; Physician and Professor of Clinical Medicine in Sir Patrick Dun's Hospital.
- FLEXNER, SIMON, M.D., Fellow of the College of Physicians of Philadelphia ; Professor of Pathology in the University of Pennsylvania.
- FOSTER, SIR WALTER, M.D., D.C.L., LL.D., F.R.C.P., M.P., Consulting Physician to the General Hospital, and Emeritus Professor of Physic in Queen's College, Birmingham.
- FOX, T. COLCOTT, B.A., M.B., F.R.C.P., Physician for Diseases of the Skin at Westminster Hospital.
- GALLOWAY, JAMES, M.A., M.D., F.R.C.S., F.R.C.P., Lecturer on Forensic Medicine ; Assistant Physician to, and Physician to the Skin Department at, Charing Cross Hospital.
- GARROD, A. E., M.A., M.D., F.R.C.P., Physician to the Hospital for Sick Children, Great Ormond Street.

- GOULD, A. PEARCE, M.B., M.S., F.R.C.S., Lecturer on Surgery at, and Surgeon to, the Middlesex Hospital.
- GOWERS, SIR WILLIAM R., M.D., F.R.C.P., F.R.S., Consulting Physician to University College Hospital ; Physician to the National Hospital for the Paralysed and Epileptic.
- GREEN, T. HENRY, M.D., Physician to, and Special Lecturer on Clinical Medicine at, Charing Cross Hospital ; Physician to the Hospital for Consumption and Diseases of the Chest, Brompton.
- GREENFIELD, WILLIAM S., M.D., F.R.C.P., F.R.M.S., F.R.S., Professor of Pathology and Clinical Medicine in the University of Edinburgh.
- GRIMSHAW, The late THOMAS W., M.A., M.D., Registrar-General for Ireland ; Consulting Physician to the Fever Hospital, Cork Street, and to Steeven's Hospital, Dublin.
- GUNN, R. MARCUS, M.A., M.B., C.M., F.R.C.S., Surgeon to the Royal London Ophthalmic Hospital, and Ophthalmic Surgeon to the National Hospital for the Paralysed and Epileptic.
- HALLIBURTON, W. D., M.D., F.R.C.P., F.R.S., Professor of Physiology at King's College, London.
- HAMILTON, D. J., M.B., F.R.C.S. Edin., F.R.S.E., Professor of Pathology in the University of Aberdeen.
- HAROLD, JOHN, M.B., B.Ch., B.A.O., Physician to St. John's and St. Elizabeth's Hospital ; Demonstrator of Medicine at Charing Cross Hospital.
- HAWKINS, HERBERT P., M.A., M.D., F.R.C.P., Physician to, and Lecturer on Medicine at, St. Thomas's Hospital.
- HEAD, HENRY, M.A., M.D., F.R.C.P., F.R.S., Assistant Physician to the London Hospital.
- HEBB, RICHARD GRAINGER, M.A., M.D., F.R.C.P., Physician and Lecturer on Forensic Medicine at the Westminster Hospital.
- HEMMETER, JOHN C., M.D., Ph.D., Clinical Professor of Medicine at the Baltimore Medical College ; Director of the Clinical Laboratory of the University of Maryland ; and Consultant to the Maryland General Hospital.
- HERRING, HERBERT THOMAS, M.B., B.S., London.
- HEWITT, FREDERICK W., M.A., M.D., Anæsthetist to H.M. the King ; Anæsthetist and Instructor in Anæsthetics at the London Hospital.
- HEWLETT, R. T., M.D., D.P.H., Professor of General Pathology at King's College, London.
- HILL, The late BERKELEY, M.B., Surgeon to, and Professor of Clinical Surgery at, University College Hospital ; Surgeon to the Lock Hospital.

- HOGG, F. S. D., Medical Superintendent of the Dalrymple Home for Inebriates.
- HOPKINS, F. GOWLAND, M.A., B.Sc., M.B., Lecturer on Chemical Physiology at the University of Cambridge.
- HORSLEY, VICTOR A. H., M.B., B.S., F.R.C.S., F.R.S., Surgeon to University College Hospital, and to the National Hospital for the Paralysed and Epileptic.
- HORTON-SMITH, P., M.A., M.D., F.R.C.P., Assistant Physician and Pathologist to the Hospital for Consumption and Diseases of the Chest, Brompton.
- HUNTER, WILLIAM, M.D., F.R.C.P., F.R.S.E., Assistant Physician to the London Fever Hospital; Joint Lecturer on Practical Medicine and Physician to the Electrical Department at Charing Cross Hospital.
- HUTCHINSON, JONATHAN, M.D., F.R.C.S., LL.D., F.R.S., Consulting Surgeon to the London Hospital, and to the Royal London Ophthalmic Hospital.
- HUTCHINSON, JONATHAN, JUN., F.R.C.S., Surgeon to the London Hospital.
- JACOBSON, WALTER H. A., M.A., M.B., M.Ch., F.R.C.S., Surgeon to Guy's Hospital.
- JAMIESON, W. ALLAN, M.D., C.M., F.R.C.P., Lecturer on Diseases of the Skin at the University of Edinburgh; Physician for Diseases of the Skin at the Edinburgh Royal Infirmary.
- JENNER, The late SIR WILLIAM, Bart., G.C.B., M.D., D.C.L., LL.D., F.R.S., Consulting Physician to University College Hospital.
- JOHNSON, RAYMOND, M.B., F.R.C.S., Assistant Professor of Clinical Surgery at University College, London; Assistant Surgeon to University College Hospital; Surgeon to the Victoria Hospital for Children, Chelsea.
- JONES, LEWIS, H., M.A., M.D., F.R.C.P., Medical Officer in Charge of Electrical Department at St. Bartholomew's Hospital.
- JONES, ROBERT, M.D., F.R.C.S., Resident Physician at, and Superintendent of, the London County Asylum, Claybury.
- KIDD, PERCY, M.A., M.D., F.R.C.P., Physician and Lecturer on Medicine to the London Hospital; Physician to the Hospital for Consumption and Diseases of the Chest, Brompton.
- LANE, W. ARBUTHNOT, M.B., M.S., F.R.C.S., Surgeon to, and Lecturer on Anatomy at, Guy's Hospital; Surgeon to the Hospital for Sick Children, Great Ormond Street.
- LANGDON-DOWN, REGINALD, M.A., M.B., B.C.
- LANGWILL, H. GRAHAM, M.D., C.M., F.R.C.P. Edin., Physician to the Leith Hospital.
- LATHAM, PETER W., M.A., M.D., F.R.C.P., Consulting Physician to Addenbrooke's Hospital.
- LAZARUS-BARLOW, W. S., B.A., M.D., B.C., F.R.C.P., Lecturer on Pathology to the Westminster Hospital.
- LEITH, R. F. C., M.A., B.Sc., M.B., C.M., F.R.C.P. Edin., Professor of Pathology and Bacteriology in the University of Birmingham.
- LITTLE, J. FLETCHER, M.B., Physician to the North London Hospital for Consumption.
- LITTLEWOOD, H., F.R.C.S., Surgeon to the General Infirmary, Leeds; Lecturer on Operative Surgery to the Yorkshire College.
- LIVEING, ROBERT, M.A., M.D., Consulting Physician for Diseases of the Skin at the Middlesex Hospital.
- LOCKWOOD, CHARLES B., F.R.C.S., Assistant Surgeon to, and Lecturer on Anatomy at, St. Bartholomew's Hospital.
- LUFF, ARTHUR PEARSON, M.D., B.Sc., F.R.C.P., D.P.H., Physician for Out-Patients to, and Lecturer on Medical Jurisprudence at, St. Mary's Hospital; Official Analyst to the Home Office.
- MCCARTHY, JEREMIAH, M.A., M.B., F.R.C.S., Consulting Surgeon to the London Hospital.
- MACCORMAC, The late SIR WILLIAM, Bart., K.C.V.O., M.A., M.Ch., D.Sc., F.R.C.S., Surgeon-in-Ordinary to H.M. the King; Consulting Surgeon to St. Thomas's Hospital.
- MACDONALD, GREVILLE, M.D., Physician for Diseases of the Throat to King's College Hospital.
- McKENDRICK, J. GRAY, M.D., C.M., LL.D., F.R.S., F.R.S.E., Professor of Physiology in the University of Glasgow.
- MACKENZIE, HECTOR W. S., M.A., M.D., F.R.C.P., Physician and Lecturer on Pharmacology and Therapeutics at St. Thomas's Hospital.
- MACKENZIE, STEPHEN, M.D., F.R.C.P., Physician to the London Hospital.
- MACLEOD, KENNETH, M.A., M.D., LL.D., F.R.C.S., Col. I.M.S., Professor of Clinical and Military Medicine to the Army Medical School, Netley.

- SEATON, EDWARD, M.D., F.R.C.P., F.C.S., Lecturer on Public Health at St. Thomas's Hospital ; Medical Officer of Health to the Administrative County of Surrey.
- SHAPTER, The late THOMAS, M.D., LL.D., Consulting Physician to the Devon and Exeter Hospital.
- SHAW, LAURISTON E., M.D., F.R.C.P., Physician to Guy's Hospital.
- SHEILD, A. MARMADUKE, M.B., F.R.C.S., Surgeon to, and Surgeon in Charge of the Throat Department at, St. George's Hospital.
- SHELLY, CHARLES E., M.A., M.D., M.R.C.P., Consulting Medical Officer at Haileybury College.
- SIBBALD, SIR JOHN, M.D., F.R.C.P. Edin., F.R.S.E., late Commissioner in Lunacy for Scotland.
- SIMON, MAXIMILIAN FRANK, M.D., late Principal Civil Medical Officer, Straits Settlements.
- SIMPSON, ALEXANDER RUSSELL, M.D., F.R.C.P. Edin., Physician to the University Clinical Ward for Diseases of Women, Royal Infirmary, Edinburgh ; Professor of Midwifery and Diseases of Women and Children in the University of Edinburgh.
- SIMPSON, W. J. R., M.D., F.R.C.P., D.P.H., Professor of Hygiene at King's College, London ; Lecturer on Tropical Hygiene at the London School of Tropical Medicine.
- SINCLAIR, THOMAS, M.D., M.Ch., F.R.C.S., Surgeon to the Belfast Royal Hospital ; Professor of Surgery at Queen's College, Belfast.
- SMITH, EUSTACE, M.D., F.R.C.P., F.R.C.S., Physician to H.M. the King of the Belgians ; Physician to the East London Hospital for Children.
- SMITH, J. LORRAIN, M.A., M.D., C.M., Professor of Pathology at Queen's College, Belfast.
- SMITH, W. JOHNSON, F.R.C.S., Surgeon to the Seamen's Hospital, Greenwich.
- SMITH, R. PERCY, M.D., F.R.C.P., Physician for Mental Diseases and Lecturer on Psychological Medicine at Charing Cross Hospital.
- SMYLY, WILLIAM J., M.D., F.R.C.P.I., F.R.C.S.I., Gynæcologist to the Adelaide Hospital, Dublin.
- SNELL, E. HUGH, B.Sc., M.D., D.P.H., F.R.S.E., Medical Officer of Health to the City of Coventry.
- SOUTHEY, The late REGINALD, M.D., Commissioner in Lunacy ; Physician to St. Bartholomew's Hospital.
- SQUIRE, The late WILLIAM, M.D., F.R.C.P., Physician to the North London Hospital for Diseases of the Chest.
- STARLING, ERNEST H., M.D., F.R.C.P., F.R.S., Jodrell Professor of Physiology in University College, London.
- STEVENSON, THOMAS, M.D., F.R.C.P., Lecturer on Medical Jurisprudence at Guy's Hospital ; Scientific Analyst to the Home Office.
- STEWART, The late SIR T. GRAINGER, M.D., F.R.S., Professor of Physic in the University of Edinburgh.
- STILL, GEORGE F., M.A., M.D., F.R.C.P., Assistant Physician for Diseases of Children at King's College Hospital, and to the Hospital for Sick Children, Great Ormond Street.
- STONHAM, CHARLES, F.R.C.S., Major R.A.M.C., Surgeon to, and Lecturer on Surgery at, the Westminster Hospital.

- WILLIAMS, SIR JOHN, Bart., M.D., LL.D., F.R.C.P., Physician-Accoucheur to H.R.H. the Princess of Wales; Consulting Obstetric Physician at University College Hospital; Emeritus Professor of Midwifery at University College, London.
- WILLS, W. A., M.D., M.R.C.P., Assistant Physician to the Westminster Hospital; Physician to the North-Eastern Hospital for Children.
- WILSON, The late SIR ERASMUS, LL.D., F.R.S., President of the Royal College of Surgeons.
- WOODHEAD, GERMAN SIMS, M.A., M.D., F.R.S.E., Professor of Pathology in the University of Cambridge.
- WRIGHT, ALMROTH EDWARD, B.A., M.D., B.Ch., Professor of Pathology in the Army Medical School, Netley.

DICTIONARY OF M E D I C I N E

A

ABDOMEN, Diseases of the.—Excluding a few peculiar affections, the diseases of the abdomen may be arranged under the following groups:—

I. Diseases of the anterior abdominal walls.

II. Diseases of the peritoneum and its folds.

III. Diseases of the organs and systems contained within the abdominal cavity, namely:—1. Stomach and Intestines; 2. Hepatic structures, including the liver, gall-bladder, gall-ducts, and vessels; 3. Spleen; 4. Pancreas; 5. Suprarenal capsules; 6. Urinary apparatus, viz. the kidneys and ureters, and the bladder; 7. Female generative organs, including the uterus and its broad ligaments, the Fallopian tubes and the ovaries; 8. Absorbent glands.

IV. Diseases of the abdominal vessels, especially the aorta and the iliac arteries.

V. Diseases of the sympathetic or other nerves contained within the abdomen.

VI. Diseases originating in connection with the cellular tissue, such as inflammation or abscess.

VII. Diseases springing from the posterior boundary of the abdomen; from the pelvis or the structures lining it; or from the diaphragm, and thence invading the abdominal cavity.

VIII. Diseases encroaching upon the abdomen from other parts, especially from the thorax.

It must be borne in mind that the groups of diseases above mentioned may be presented in various combinations, two or more structures being not uncommonly implicated at the same time.

Several of the abdominal organs are very liable to so-called *functional disorders*, and these disorders often give rise to prominent and troublesome symptoms, which are urgently complained of by the patient. Definite *organic diseases* are also of common occurrence, many of them being of a very serious character. Some of the organs contained within the abdomen are liable to *malposition* or *displacement*, as well as to *malformations*, these being either congenital or acquired; while the hollow viscera may be the seat of *obstruction* or *accumulations* of different kinds. Each of these conditions may become clinically important.

Abdominal lesions are frequently purely *local* in their origin, but several of them are but local manifestations of some more *general* condition, being associated either with certain acute febrile diseases, e.g. typhoid fever; or with such affections as cancer or tuberculosis. Again, symptoms connected with

the abdomen may depend upon disease in some remote part of the body; or some of its organs may become the seat of morbid changes as a consequence of disease in other structures. For instance, vomiting is frequently associated with cerebral disorders; while affections of the heart are liable to lead to troublesome symptoms, as well as to serious lesions, in connection with many of the abdominal viscera. Lastly, a morbid condition of one organ within the abdomen may be the direct means of originating *secondary* mischief in other structures.

FREDERICK T. ROBERTS.

ABDOMEN, Examination of.—The neglect of submitting patients to a satisfactory physical examination is a frequent source of error in diagnosis in cases of abdominal disease, and there ought to be no hesitation or delay in resorting to this method of clinical investigation whenever it seems called for. The precise course to be pursued must vary according to circumstances, but the following outline will serve to indicate the plan of procedure ordinarily required.

First, there are certain modes of examination which are applied to the abdomen externally, including *Inspection*; *Palpation* or *Manipulation*; *Mensuration*; *Percussion*; and *Auscultation* (see **PHYSICAL EXAMINATION**). Of these, inspection, palpation, and percussion are by far the most important, and have, in the large majority of cases, to be relied upon for the information required. In exceptional instances *Succession*, or shaking the patient, proves serviceable, by bringing out certain sensations or sounds. In order to carry out these methods properly, it is necessary to expose the abdomen sufficiently, due regard being paid to decency in the examination of females; to place the patient in a suitable position; and to see that the muscles of the abdominal walls are duly relaxed. The best position is for the patient to lie on the back, in a half-reclining attitude, with the head and shoulders well raised, and the thighs and knees more or less flexed. This posture serves to relax the abdominal muscles, which may be further aided by taking off the patient's attention by conversation or in other ways, as well as by directing him to breathe deeply. The position, however, has often to be varied in the investigation of particular cases, and much information is frequently gained by noticing the effects of a change in posture.

The objective conditions which may be revealed by the modes of examination thus far considered are as follows:—1. The state of the superficial structures. 2. The size and shape of the abdomen, generally and locally, as indicating any alteration in the volume of the ordinary contents of the abdomen, or the presence of some new or fresh element, such as dropsical fluid or a tumour. 3. The characters of the abdominal respiratory movements; and the presence of any unusual sensations during the act of breathing, such as friction-fremitus. 4. The sensations experienced on palpation and percussion over the abdomen, either as a whole, or in any particular part of it, such as its mobility, degree of resistance, regularity, consistence; as well as the presence of certain peculiar sensations, e.g. fluctuation, or hydatid-fremitus. 5. The presence and characters of any pulsation. 6. The occurrence of abnormal movements within the abdomen, as those of a fetus. 7. The sounds elicited, generally and locally, on percussion. 8. The presence of certain sounds within the abdomen, heard on auscultation, such as friction-sounds; murmurs connected with aneurysm or due to pressure on an artery; or murmurs and sounds associated with the pregnant uterus.

Here it may be remarked that it is highly important in all cases to see that no accumulation of feces exists within the bowel, and that the bladder is properly emptied, otherwise very serious mistakes are liable to be made. Purgatives and enemata are needed in order to remove any fecal collection. The urine should also be properly tested in every instance; and much information may often be gained in the investigation of affections of the alimentary canal, from a personal inspection or more complete examination of feces or vomited matters.

Secondly, it not uncommonly happens that special modes of examination have to be applied to particular organs within the abdomen, in order to arrive at a diagnosis with any certainty. Thus it is sometimes requisite to have recourse to the use of the exploring trocar or aspirator; or to the administration of chloroform. The latter may afford direct information in certain abdominal conditions, and it may also materially assist in carrying out other methods of exploration. The use of Röntgen rays may assist in the diagnosis of renal calculus, though this method of examination is of less use in abdominal disease than in disorders of the chest or of the limbs (*see* RÖNTGEN RAYS). In certain cases more serious operative procedures have to be adopted for diagnostic purposes. *See* PARACENTESIS.

The abdomen has been, for purposes of description, artificially divided by anatomists into regions, and the seat of any local morbid condition can thus be defined and described. These regions are thus named: epigastric, hypochondriac, hypogastric, iliac, lumbar, and umbilical. *See* plate in PHYSICAL EXAMINATION.

The following is a summary of the usual procedure:—

INSPECTION.—Herniæ, inflammations, new growths &c. in wall. Pigmentation, lineæ albicantes. Thin, fat; shape, sunken, distended uniformly; more in the central regions (pointed abdomen); or more in the flanks (broad abdomen); local swelling; distended stomach (bagpipe tumour); coils of intestine; tumours; visible peristalsis; point of ending of movements; condition of umbilicus,

stretched transversely, depression obliterated, protruding, translucent; movements of wall, impaired locally or generally, falling in; condition of skin and superficial veins.

PALPATION.—Flaccidity; tension of wall from distension; general rigidity; local resistance; tenderness, local, general, superficial, deep; gurgling (e.g. right iliac fossa); succussion-splash; friction; fulness; swelling; tumour.

In the case of a tumour, note its position, size, shape, surface, edges, mobility, consistence, pulsation, occasional hardening or contraction, ballottement, fetal parts and movements.

PERCUSSION.—Locality of any change in resonance; effect of change in posture.

AUSCULTATION.—Friction; vascular bruit; foetal heart.

Liver and gall bladder . . .	} The position and condition of the abdominal viscera, and of tumours, to be ascertained by inspection, palpation, percussion, the exact limits being noted according to the regions of the abdomen, and by measurements from fixed points, or recorded on diagrams.
Spleen . . .	
Stomach . . .	
Colon . . .	
Kidneys . . .	
Bladder . . .	
Uterus or ovaries . . .	

RECTUM AND ANUS.—Physical examination, if necessary. Place patient on left side, thighs well drawn up. Inspect anus, natural, contracted, patulous; note any abnormal condition. Palpate anus and surrounding parts; examine any swelling; probe fistulæ; extent; internal opening. Pass finger well oiled; note excessive pain and any abnormality within bowel. Try gently to pass finger into or through any stricture or new growth while patient 'bears down,' and to move it among surrounding parts; bleeding excited; pass duckbill or other speculum (if necessary), and examine whole circumference of bowel. Bougies may be passed through a stricture with care. *See also* BLADDER, EXAMINATION OF; STOMACH, EXAMINATION OF; UTERUS, EXAMINATION OF.

FREDERICK T. ROBERTS.

ABDOMEN, Exploration of.—*See* PARACENTESIS.

ABDOMEN, Tumours of.—*See* ABDOMINAL CYSTS; and PHYSICAL EXAMINATION.

ABDOMINAL ANEURYSM.—Abdominal aneurysm includes aneurysm of the aorta, and of any of its branches within the abdomen.

Aneurysm of the Abdominal Aorta is essentially a disease of middle age. Of 59 cases collected by Crisp, 33 were under the age of forty. It is more common in the male than in the female sex, in the proportion of about 8 to 1; and is usually traceable to strain or injury; not infrequently it is embolic in origin (*see* ANEURYSM). The aneurysm is most frequently located in that portion of the vessel included between the aortic opening in the diaphragm and the origin of the superior mesenteric artery, being seldom met with below this point. In this situation the tumour is deeply seated; liable to tension from the crura of the diaphragm; and likely to involve the great splanchnic nerves, the semilunar ganglia, and the solar plexus. Aneurysm of the abdominal aorta is usually of the *false* variety; and, as contrasted with thoracic aneurysm, it is less often associated with extensive atheroma of the aorta, and

with fatty or other structural disease of the heart. The symptoms referable to excentric pressure are also fewer, and, with the exception of pain, are less urgent than in the thoracic variety.

SYMPTOMS AND SIGNS.—Of the symptoms, *pain* is the most characteristic and the most urgent; it is of two kinds, which are not, however, necessarily associated. The first is due to the irritation and stretching of the nerves above mentioned. It is essentially neuralgic; it is intermittent, lancinating, and paroxysmal,—encircling the body like a girdle, or radiating through the abdomen, back, pelvis, and base of the thorax, and not infrequently into either groin or testicle. The accession is sudden, and usually attributable to some definite cause of vascular excitement. The duration extends over a period varying from one to three hours, rarely longer; and the cessation is equally abrupt, leaving the patient in a state of exhaustion, but quite free from actual suffering. The second kind of pain referred to is continuous and boring; fixed at a particular point of the vertebral column; aggravated by pressure at this point, by active movement or stamping, and by gently turning the patient half round upon his axis in the standing posture; but relieved by assuming the prone position or by leaning forward. Pain so characterised is pathognomonic of erosion of the vertebræ. Pressure of an aneurysm may affect the functions of several organs within the abdomen. Thus *jaundice* may result from pressure upon the hepatic, or common biliary duct: it is, however, more frequently due to an aneurysm of the hepatic, or of the superior mesenteric artery. *Interference with the urinary secretion*, and the consequences thereof, from pressure upon the renal vessels; *dysphagia*, from pressure upon the œsophagus; *vomiting*, from obstruction of the pylorus; *displacement* of the liver forwards, or of the heart upwards—though rare symptoms—may be likewise due to the same cause. The radial pulse is not often affected. Symptoms of *constitutional irritation* and impaired nutrition are rarely exhibited, and appear only at the termination of protracted and painful cases, associated with great suffering and want of sleep.

Physical signs.—A tumour can often be felt in the epigastric and left hypochondriac regions. It is smooth, rounded, and elastic; and tends to descend. It communicates to the hand alternate movements of lifting and expansion with increasing tension, and of subsidence with relaxation. The pulsation is all but invariably single, and synchronous with the radial pulse; it is limited to the tumour, and occasionally accompanied by thrill. Pressure upon the aorta below the tumour will increase the force of impulse, diminish or abolish the thrill, and arrest the collapse. In a few recorded examples the tumour was hard and uneven on the surface, and non-expansile; and in a still smaller number no pulsation was perceptible, the aperture of communication with the artery having been blocked, or the vessel compressed on the proximal side by the growth of the aneurysm itself. Owing to the position of the hollow viscera in front, and the mass of lumbar muscles behind, the evidence from percussion is less conclusive in regard to abdominal than thoracic aneurysm. If, however, the abdominal muscles be relaxed, and the stomach and bowels free from flatus, absolute dulness to the extent of the tumour may be detected. A sound, single or double, as distinguished from a murmur, is rarely heard in

front in connection with abdominal aneurysm; whereas the existence of a sound, usually double, without a murmur, at a point on the posterior wall of the abdomen corresponding to the tumour, is the rule, and when detected, is of the utmost diagnostic value. A murmur in the recumbent posture is rarely absent in front; it is single, blowing, prolonged, post-systolic, and not transmitted into the vessel beyond. It may, however, be musical, or it may present both these characters, but at different points of the tumour; in one instance it was of a buzzing quality. Should the aneurysm have taken an exclusively backward course, which is the exception, a single murmur, not audible in front, may be heard in the back. In a few recorded cases a double murmur has been heard over the aneurysm in front. In the erect posture the murmur is usually suspended; but in a few published cases it was audible in both the erect and the recumbent posture, and in one at least in the erect posture only. These peculiarities depend upon the various conditions of the sac, its orifice, and its contents. A small aneurysm involving the posterior wall of the vessel only, and eroding the vertebræ, may be latent as to physical signs, though attended with severe fixed pain in the back, and weakness of the lower extremities. In some cases a slight retardation of the pulse in the femoral arteries has been noted.

DIAGNOSIS.—The diagnosis of abdominal aneurysm has reference mainly to its physical signs. The higher the aneurysm the more obscure will be the physical signs and the more marked the evidences of pressure. Strong pulsation of the aorta, simulating that of aneurysm, may exist in connection with hysteria, uterine or intestinal irritation, dyspepsia, or marked æmia. But in all these cases, irrespective of the positive and specific evidence presented by each, throbbing exists throughout the aorta, and is propagated into the main arteries of the lower limbs, whereas it is localised and expansile in aneurysm; and a careful exploration of the aorta—if necessary, under the influence of chloroform—will show that, in the case of a pulsating aorta, the dimensions of the artery are at all points normal. In these cases, too, although a murmur may be produced by strong pressure with the stethoscope, it does not exist when pressure is withdrawn. A cancerous or other tumour pressing upon the aorta may likewise produce a murmur, and may exhibit pulsation communicated from the aorta; but in most cases both these phenomena are promptly arrested by placing the patient in the ‘knee and elbow’ position. A tumour, in that position, will fall away from the vessel; whereas the pulsation of an aneurysm will often be more easily felt. The fixed local pain in the back, aggravated by pressure and motion, may be simulated by ordinary lumbago; and the paroxysmal visceral pain, by biliary colic. The differential diagnosis must rest upon the specific evidence in each case.

Aneurysm of the Branches of the Abdominal Aorta.—The branches most liable to aneurysm are the common iliacs and their divisions; the coeliac axis and its branches; the renal, and the superior mesenteric. *Aneurysm of the Iliac Arteries* belongs to the domain of surgery, and will not be further referred to here. *Aneurysm of the Celiac Axis* and of its branches of division, and of the *Superior Mesenteric Artery*, are, in addition to the ordinary signs, characterised by mobility of the tumour; and the first two varieties by the occurrence

of jaundice, hæmatemesis, and mælena, from pressure. *Renal* aneurysm may cause infarction in the kidney, or venous congestion by pressure on the renal vein.

DURATION AND TERMINATIONS.—The duration of life in abdominal aneurysm in a number of cases observed varied from fifteen days to eleven years. Death occurs usually: (1) by rupture of the sac into (a) the retro-peritoneal tissues, unless a secondary sac be formed; (b) the cavity of the peritoneum; (c) the left pleural cavity or corresponding lung; (d) the intestinal canal; (e) the inferior vena cava; (f) the psoas muscle; (g) the pelvis of the kidney; (h) the spinal canal; or (i) the ureter, biliary passages, or œsophagus—the order given representing the relative frequency of the fatal result; or (2) by exhaustion or syncope. The duration of life after the rupture of the aneurysm has ranged from a few minutes to several weeks. A consecutive false aneurysm, retroperitoneal in site, is specially characterised by feeble pulsation of the tumour, and diminished or arrested circulation in the femoral artery of one or both sides.

TREATMENT.—The *curative* treatment of abdominal aneurysm may be considered under three heads—*operative*, *postural* and *dietetic*, and *medicinal*. *Operative* treatment consists in pressure applied to the aorta on the proximal side of the sac, by means of tourniquets, so as completely to stop the circulation. The bowels should be first well moved and freed from flatus; and during the continuance of pressure the patient should be kept under the influence of chloroform or ether. As a rule, compression should not be employed above the level of the duodenum. Five cases, if not more, in which a cure was effected by these means have been reported. The object sought to be attained being that of effecting rapid coagulation in the sac, the period during which pressure needs to be continued in these cases varies from three quarters of an hour to ten hours and a half. Pressure on the distal side is dangerous from its liability to cause rupture. Under all circumstances, pressure must be used with care, as inflammation of the peritoneum or of the bowels has been known to result from it. Galvano-puncture, and the introduction of foreign bodies, such as iron wire and horsehair, into the aneurysmal sac have also been employed. In a small proportion of cases the latter method has been attended with a favourable result, but less often in abdominal than in thoracic aneurysms.

Bellingham introduced the plan of treatment by *posture* and *restricted diet*. Under this plan perfect repose of mind and body is, as far as practicable, to be maintained; the bowels being kept moderately free, and the dietary restricted to 40 oz. including solids and liquids. According to the method of the late Mr. Tufnell, which is based upon the same principle, but is more rigid, the patient is strictly confined to the horizontal posture for a period varying from eight to thirteen weeks, as determined by the effect upon the aneurysm, movement in bed being effected with caution; whilst, by a special arrangement, the bowels and the bladder may be evacuated without disturbance of the body. For breakfast, 2 oz. of white bread and butter, with 2 oz. of cocoa or milk, are allowed; for dinner, 3 oz. of meat, with 3 oz. of potatoes or bread, and 4 oz. of water or claret; and for supper, 2 oz. of bread and butter, and 2 oz. of milk or tea. The total amount in the twenty-four hours would be: solids 10 oz.,

liquids 8 oz. This system is not often rigidly enforced, and is not so frequently employed as formerly.

Of the various *medicinal* agents used with a view to favouring or effecting a deposit of laminated fibrin in the sac, chloride of calcium (10 to 15 grs. thrice daily) is the best, though acetate of lead and iodide of potassium are often used. Iodide of potassium may be given in doses of 10 to 20 grs. thrice daily, with a view to reducing vascular tension, and thereby relieving pain and promoting deposition in the sac, whilst perfect rest in the recumbent posture and a restricted dietary are observed. The intramuscular injection of 20 to 80 c.c. of a sterilised 1 to 3 per cent. solution of gelatine in 1 per cent. solution of sodium chloride on alternate days has been recently employed, but with very varied success. In all cases the allowance of liquids must be reduced to the lowest possible standard, whilst excretion is promoted. Alcoholic stimulants may be given in small quantity and at long intervals, if the pulse exhibit debility and the patient complain of a sensation of sinking; otherwise they should be prohibited.

The application of a few leeches, followed by a warm poultice, is very efficacious in relieving pain. The hypodermic use of morphine is still more rapidly effective. See THORACIC ANEURYSM.

C. J. NIXON.

ABDOMINAL CYSTS.—This article includes a short description of cystic tumours of the abdomen, not described under other headings.

1. **Allantoic.**—See 11. URACHAL CYSTS.

2. **Dermoid Cysts.**—Dermoid cysts are occasionally found in the peritoneum without the existence of an ovarian dermoid; it is not improbable that in reality the cyst originated in the ovary, but became detached and secondarily adherent elsewhere. When an ovarian dermoid ruptures it may give rise to *implantation cysts* in various parts of the peritoneal cavity.

3. **Hæmorrhagic or Sanguineous Cysts.**—Hæmorrhagic cysts are occasionally met with in the abdomen. In rare instances they are due to softening and extravasation of blood into sarcomata.

Simple Sanguineous Cysts may be due to traumatism and are usually found around the pancreas, in the transverse mesocolon, or mesentery. They then closely resemble peripancreatic cysts; but they may arise elsewhere; in one case, examined after death, a large hæmorrhagic cyst arose in the pelvis.

The symptoms are much the same as those of pancreatic cysts. The proper treatment is incision and drainage.

4. **Hydatid Cysts.**—See ENTOZOA.

5. **Hydronephrosis.**—See HYDRONEPHROSIS.

6. **Mesenteric Cysts.**—These cysts are rare. They may be divided into (1) *Lymphatic*, the most frequent form; either serous or chylous, due to dilatation of lymphatic vessels or to dilatation and degenerative changes in lymphatic glands; (2) *Hæmorrhagic*, usually due to traumatism, but also possibly the result of hæmorrhage into lymphatic cysts or into growths; (3) *Hydatids*; (4) cases thought to be congenital, such as dermoids, and cysts derived from the Wolffian body; (5) possibly some mesenteric cysts are due to developmental errors in the intestine.

Mesenteric cysts are more often seen in females. The characteristic signs are a fluctuating, very

movable tumour near the umbilicus with a band of resonance in front of it, due to the intestine. Though there may be no symptoms, colic, diarrhoea, or constipation is generally present, while sometimes acute obstruction occurs.

The *diagnosis* is difficult: ovarian, hydatid, and pancreatic cysts must be thought of, and solid tumours or a floating kidney borne in mind.

The *treatment* is surgical, viz. removal or incision and drainage.

7. **Omental Cysts.**—Hæmorrhagic cysts of the omentum have been met with. Dermoid cysts may be implanted on the mesentery and are derived from ovarian cysts of the same nature. It is possible that an ovarian cystadenoma might be torn away from its original site and become adherent to the omentum. In very rare instances the omentum contains a multitude of small cysts, possibly lymphatic.

8. **Ovarian Cysts.**—See OVARIES, Diseases of.

9. **Pancreatic Cysts.**—Under this heading are included cysts which clinically appear to arise in or from the pancreas. Cystic dilatation of the pancreatic duct may be due to obstruction and constitute a true pancreatic cyst. Cysts may possibly be due to hæmorrhage and inflammatory processes arising inside the pancreas, or in rare cases to cystic change in a new growth. These true pancreatic cysts may be single and large, multilocular and of considerable size, or multiple and small.

Probably a considerable proportion of what appear to be pancreatic cysts clinically are in reality peripancræatic cysts and due to localised peritonitis in the lesser sac of the peritoneum. The inflammatory process closes the foramen of Winslow and so leads to an encysted peritoneal effusion in the immediate neighbourhood of the pancreas. What the numerical relation of true pancreatic to peripancræatic cysts is it is difficult to say at the present time, but the belief that a large proportion of those requiring treatment are peripancræatic is gaining ground.

ÆTIOLOGY.—Injury, straining, and inflammation of the pancreas are the usual antecedent conditions.

SITUATION.—CONTENTS.—The cysts most often arise from the tail of the pancreas and may project below the stomach, above it, or push that viscus forwards. The cyst may reach a large size and contain many quarts of fluid. The fluid may be clear, but is more often dark brown from altered blood; it is alkaline, of a sp. gr. 1010–1020, and contains the fat-splitting, amylolytic, and proteolytic ferments of the pancreas; the presence of the last named is of most importance from a diagnostic point of view, inasmuch as the other two may be met with in effusions elsewhere.

CLINICAL FEATURES.—There is a tense tumour in the upper part of the abdomen, usually in the epigastrium or left hypochondrium. It is slightly movable, and, if the stomach be distended, can be shown to arise behind that organ. There may be no symptoms, but, as a rule, the patient suffers from attacks of pain with vomiting and collapse. Pressure-symptoms, when the cyst is large, may occur; jaundice is rare. Sometimes the progress is rapid, but more often the condition is chronic; considerable alteration in the size of the cyst, both enlargement and diminution, may be noted.

DIAGNOSIS between true and peripancræatic cysts is impossible until the anatomical conditions are examined, and even then may not be conclusive during life. Pancreatic cysts must be distinguished

from hydronephrosis on the left side, a dilated gall-bladder, hydatid cysts, and sometimes from large ovarian cysts.

PROGNOSIS.—If left alone the larger cysts may rupture into the general peritoneal cavity with fatal results.

TREATMENT.—Tapping the cyst with a trocar through the abdominal walls is a very dangerous proceeding and should never be countenanced. Laparotomy with incision and drainage of the cyst is the proper course unless it is found possible to remove it entirely.

10. **Retro-peritoneal Cysts.**—Other than pancreatic retro-peritoneal cysts are rare; they may be hydatid, derived from the remains of the Wolffian body, or pseudo-cysts due to softening of retro-peritoneal sarcoma or suprarenal growths. Retro-peritoneal collections of blood, chyle, or urine have been occasionally seen, usually after traumatism. The clinical features of retro-peritoneal cysts are those of a deep-seated tumour; they may easily be mistaken for a pancreatic cyst or a hydronephrosis.

Their *treatment* is removal by Laparotomy.

11. **Urachal Cysts.**—The urachus, that part of the allantois which runs in front of the peritoneum as a fibrous cord between the urinary bladder and the umbilicus, not uncommonly shows minute cystic dilatations. In rare instances large cysts develop; they occur in either sex. The cyst is situated in the middle line between the umbilicus and the pubes and in front of the peritoneum. A communication with the urinary bladder may exist. The walls of the cyst contain smooth muscular fibres—the expanded muscular walls of the urachus. The treatment of these cysts is complete removal, or, if this is impossible, incision and drainage.

Under the name Allantoic cysts, Lawson Tait and Robinson described a different condition occurring in women, which they ascribed to an abnormal process of development on the part of the allantois. Alban Doran, however, makes it clear that these so-called allantoic cysts are really encysted tubercular peritonitis, the infection spreading from the Fallopian tubes.

H. D. ROLLESTON.

ABDOMINAL WALLS, Diseases of.—Most of these are but local forms of diseases which are fully described in other parts of this work. The parietal peritoneum will be excluded from consideration, as its morbid conditions are treated of separately.

1. **SUPERFICIAL AFFECTIONS.**—*a.* The skin covering the abdomen may be the seat of various eruptions. The rash of typhoid fever is chiefly observed over this region. *b.* When the abdomen is greatly enlarged, its cutaneous covering becomes stretched and thinned, often presenting a shining appearance; or it may even give way, so that it exhibits superficial cracks or fissures. If it has been distended for a considerable time or on several occasions, as after repeated pregnancies, the skin becomes impaired in its nutrition, and is often the seat of permanent white lines or furrows—*lineæ albicantes*. In this connection allusion may be made to the umbilicus, which, in certain forms of distension of the abdomen, may become pouched out, everted, or actually obliterated. *c.* The superficial veins frequently become enlarged and tortuous,

when the return of the blood which is normally conveyed through them is in any way impeded. *d.* The cutaneous sensibility over the abdomen is sometimes materially altered. In certain nervous diseases it may become more or less impaired or lost; but the most important deviation is a marked increase of sensibility — *hyperæsthesia* — which is occasionally observed in hysterical females, and which may simulate more serious affections, particularly peritonitis, especially if it is accompanied with symptoms of much depression. This condition is characterised by extreme *superficial* sensibility or tenderness of the abdomen, the slightest touch being resented; but if the patient's attention can be taken off, and deep pressure be then made, this is borne with little or no indication of distress. The exact position of the tenderness, the aspect of the patient, the presence of other symptoms indicative of hysteria, and the absence of pyrexia usually serve to distinguish this affection from others of a graver nature. The surface of the abdomen may also be affected with neuralgia, which is sometimes very severe.

2. **SUBCUTANEOUS ACCUMULATIONS.**—*a.* The chief morbid condition coming under this head is *œdema* or *dropsy* of the subcutaneous tissue. This generally follows anasarca of the legs, and may be associated with ascites. The fluid tends to collect especially in the lower part of the abdominal walls and towards the flanks. The skin often presents a white pasty aspect; the abdomen may be more or less enlarged; the umbilicus appears depressed and sunken, if the *œdema* extends up to this level; the superficial structures pit on pressure, and yield the peculiar sensation of dropsical tissues; and the percussion-note is frequently muffled. *b.* The abdominal subcutaneous tissue is, in many persons, the seat of an abundant collection of fat, which may be important from causing apparent enlargement, and simulating or obscuring other more serious morbid conditions which enlarge the abdomen. *c.* In rare instances gas accumulates under the skin in this region, constituting *subcutaneous emphysema*. The abdomen then appears to be enlarged, but the condition is readily recognised by the peculiar crackling or crepitant sensation felt on digital pressure; the resonant or tympanitic sound elicited by percussion; and the dry crepitant sound heard when pressure is made with the stethoscope.

3. **AFFECTIONS OF THE MUSCLES AND APONEUROSSES.**—*a.* The abdominal walls may be the seat of muscular rheumatism, which is particularly likely to follow undue straining, such as that caused by violent coughing or vomiting. It is characterised by pain, sometimes severe, evidently located in the muscular and tendinous structures, accompanied with much soreness and tenderness. The affected parts are kept as much at rest as possible, and any action which disturbs them materially aggravates the pain. *b.* As the result of violent strain, the muscular or aponeurotic tissues may be more or less torn or ruptured, or the normal openings enlarged (separation of the recti). As a consequence a protrusion of some internal structure is likely to take place, forming a hernia. *c.* The abdominal muscles are liable to be the seat of spasmodic contraction, cramp, or rigidity. These disorders are not uncommonly excited in sympathy with grave disturbance of the alimentary canal, as in cholera. In certain painful internal affections, also, some of the abdominal muscles are occasionally kept in a

state of more or less rigid tension, as if they were involuntarily contracted in order to protect the diseased parts underneath from injury. The spasmodic contractions in tetanus not infrequently cause great suffering over the abdomen. *d.* On the other hand, the abdominal muscles are occasionally paralysed, as the result of central nervous disease. The movements of respiration are then altered in character; while the expulsive acts in which the abdominal muscles naturally take part are much interfered with.

4. **RELAXED ABDOMINAL WALLS.**—All the structures forming the walls of the abdomen are often in a relaxed and flabby state, yielding to any pressure from within, so that the abdomen becomes enlarged and prominent, especially if, as is frequently the case, this condition is associated with much flatulence. It materially weakens the act of defecation, and promotes constipation.

5. **INFLAMMATION AND ABSCESS.**—Local inflammation may be set up in any of the abdominal structures, and this may terminate in suppuration and the formation of an abscess. Purulent accumulations from within, as in cases of perityphlitis and suppuration in the gall-bladder, as well as certain abscesses originating in disease of bones or joints, may likewise extend among the tissues of the abdominal walls, causing thickening and induration, or may make their way outwards, directly or through a sinus. Subsequently permanent sinuses or fistulæ may be left.

6. The abdominal wall may be the seat of *extravasation of blood*; and various kinds of *tumour* or *new growth* may form in its structures.

FREDERICK T. ROBERTS.

ABORTION.—The act of abortion signifies the expulsion of the contents of the pregnant uterus before the seventh month of gestation. An abortion is a fœtus prematurely expelled. See MISCARRIAGE.

ABSCESS (*abscedo*, I depart).—SYNON.: Fr. *Abcès*; Ger. *Abscess*, *Eitergeschwulst*.

DEFINITION.—A circumscribed collection of pus. Circumscription is the characteristic feature which distinguishes 'abscess' from 'diffuse suppuration' (purulent infiltration), which will also be considered in this article.

VARIETIES.—Two varieties of abscess are described—the *acute* and the *chronic*, but there is little besides the name common to the two conditions.

A. Acute Abscess.—**ÆTIOLOGY** of Acute Suppuration.—Suppuration is the result of the action upon the tissues of certain irritant substances. The irritant must be of considerable intensity, must act continuously for some time, and must have the power of inhibiting the formation of fibrin or of dissolving any that is formed, together with small portions of tissue.

In the vast majority of cases acute suppuration is excited by the growth of micro-organisms in the tissues. Some microbes are only rarely associated with the formation of pus; others are constantly met with in this connection. The latter, along with such of the former as are not known to occur in other morbid conditions, are grouped together under the title of *pyogenic* organisms, since their usual, though not invariable, characteristic is the production of pus. Of these different species the *Staphylococcus pyogenes aureus* is that most often found; the *Staphylococcus pyogenes albus* is next in fre-

quency, followed by the *Streptococcus pyogenes* (figs. 1 and 2). The staphylococci of one or other variety seem to occur about four times as often as the streptococcus, while the two species are found mixed in 5 per cent. of all cases. Suppuration due to mixed infections is often very severe. Cases due to staphylococci are usually circumscribed and end in abscess, while the streptococcus is specially associated with diffuse processes, and is said to be the organism most commonly found in secondary pyæmic abscesses.

The *Staphylococcus aureus* forms in its growth a continuous supply of irritant substances, among

FIG. 1.—Micrococci in capillaries of kidney in Multiple Septic Abscess. Showing masses of cocci like *Staphylococcus pyogenes aureus*. $\times 800$ diam.

FIG. 2.—Streptococci of Suppuration.—Dried pus from an empyema of some duration. Showing chains of streptococci, some of which are swollen, probably from degenerative changes. $\times 800$ diam.

which ammonia and trimethylamine have been recognised; it also gives rise to a toxin (*phlogosin*), which can by itself excite suppuration. Moreover, it has the power of peptonising substances with which it is in contact, probably by means of an enzyme, and it can thus prevent the appearance of fibrin and of small sloughs in the fluid exudate. But this cannot be the sole means by which such a result is brought about, for the *Streptococcus pyogenes* is not known to peptonise; nor do many of the other germs less frequently associated with suppuration. Possibly leucocytes have peptic power.

The proof that these micro-organisms cause suppuration is absolute. With the exception of the rare

instances of aseptic suppuration, of which mention will subsequently be made, one or other is constantly present in pus; they have been cultivated through several generations, the resulting cultures have been inoculated upon animals and have caused suppuration, and from these lesions they have been recovered in pure culture. Finally they have been experimentally inoculated upon man, with similar results.

On the other hand, the mere presence of pus-organisms in the blood or tissues is not sufficient to excite suppuration, as is evident from cases of puerperal septicæmia and other forms of this disease, in which pyococci are eliminated with the milk, urine, &c., but no abscess is anywhere formed. Unless certain circumstances favourable to the cocci exist in an infected person, they die out or are eliminated. Until the pyococci were discovered, these predisposing circumstances were regarded as the causes of suppuration.

In the first place, to excite suppuration the cocci must come to rest in some spot. Then ensues a struggle between them and the tissues. Man is only moderately predisposed to suppuration: the predisposition doubtless varies with the individual and may be increased by depression of health from any cause, especially by certain diseases, e.g. diabetes, chronic renal disease, and acute fevers; and by chronic intoxication, such as alcoholism. The point at which the cocci come to rest appears to be an important factor, for all tissues do not seem equally susceptible. Local tissue-susceptibility may be increased by injury, by exposure to cold or wet, or by a previous attack of inflammation. The pyococci, on their side, must possess certain qualities, to enable them to prevail. They must be sufficiently virulent to overcome the resistance of the tissues in which they settle—and there are no organisms which seem more liable to attenuation by unfavourable environment—and they must be in sufficient numbers, for ‘resistance’ means that the tissues can dispose of a certain number of bacteria of a given virulence. They are also greatly favoured by circumstances which afford them protection from the healthy tissues until they can form, *in loco*, sufficient toxin to protect themselves. Such protection may, for example, be afforded by envelopment in a bit of blood-clot, which is often already saturated with their products.

The possibility of the occurrence of ‘aseptic’ suppuration, i.e. of the formation of pus from causes other than micro-organisms, has been much debated, but it is probable that it can be induced experimentally, and it may rarely occur clinically. Competent observers have failed to find bacteria in a few cases of suppurating hydatids and in cases of chancrous buboes which, when opened, have assumed the characters of soft chancres. Most observers regard the exudation induced by the injection of turpentine, croton oil, ammonia, and other substances as ‘pus;’ others decline to give it this name. Lastly the injection of some toxins (freed from germs)—such as phlogosin and cadaverin—or of the dead bodies of certain bacteria, e.g. boiled tubercle-bacilli (Koch), will induce suppuration. It is characteristic of such ‘suppuration’ that it soon ceases to extend.

HABITAT OF PYOGENIC GERMS.—These microbes are very widely diffused, being often found in dirty water and in dust. Staphylococci are common in the skin and frequently occur along with streptococci, in the mouth, pharynx, and vagina. Pyococci

are specially frequent upon the hands of those who have to deal with wounds.

MODE OF ENTRY INTO THE BODY.—Usually they enter through a lesion, possibly quite minute, of skin or mucosa, but they may enter through unbroken skin, being pressed into and growing up the orifices of glands (sebaceous, mammary). It appears probable that, like other particles, they may pass through uninjured mucous membranes. In a wound of any depth, the infection may affect primarily any layer of the tissues affected, and this may suppurate while the rest heals. From the point of entry the organisms may be carried by the lymph- or blood-stream, and thus deposited in distant parts. The disturbance at the point of entry may be very slight or nil.

RESULTS OF LOCAL INFECTION BY STAPHYLOCOCCUS AUREUS: FORMATION AND ANATOMY OF ACUTE ABSCESS.—When the cocci settle at a spot under conditions permitting their development, they begin to multiply and to excrete their irritants. The result is an inflammation which passes more or less rapidly through all the usual stages, dilatation of vessels with retardation of the blood-stream and margination and free migration of leucocytes being found in the immediate neighbourhood of the cocci, while the earlier stages are seen in the outer zone of the inflamed area. In highly cellular tissues (kidney, liver) a clear area of coagulation-necrosis often forms round the cocci; but in connective tissue this is not evident. In either case the cocci pass outwards from the point of inoculation and the leucocytes press inwards towards this point. It appears that the substances formed by the bacteria exert an attractive influence (*positive chemotaxis*) upon the leucocytes, which are thus drawn towards the seat of infection (*see* CHEMOTAXIS). Soon cocci and leucocytes become mixed up; many of the organisms are ingested by leucocytes and by swollen fixed cells, others remain free. The capillaries at the centre become thrombosed and together with the tissue-elements are peptonised and removed; their place is then occupied by fluid containing numerous leucocytes and cocci. So long as free cocci pass outwards—which they do chiefly along the lines of vessels and their accompanying lymphatics—spread of the inflammation and formation of fresh foci in the neighbourhood of the primary lesion continue. These secondary foci, as they enlarge, usually coalesce with the primary cavity. After a time the cocci are hemmed in by leucocytes, and granulation-tissue forms in which no micro-organisms are found. Enlargement of the abscess may, however, still go on under the influence of tension due to the increasing quantity of fluid poured into it, to interference with the circulation in the surrounding tissues, and to softening of these by the inflammatory exudation. Extension takes place in the direction of least resistance—towards a free surface when possible—but when pus forms beneath a dense fascia, which is traversed by few blood-vessels or lymphatics and is difficult to soften, it often burrows for a considerable distance before reaching the surface. The term ‘least resistance’ implies not only slighter mechanical obstacles but also facility of passage for cocci. Finally the fluid exudation lifts up the epidermis, which softens and gives way, and the abscess empties itself more or less completely. The elasticity of the tissues around at once causes great diminution of the size of the cavity, which rapidly becomes filled up with

granulation-tissue. This is gradually converted into fibrous tissue; and finally the epidermis grows over the surface and covers it.

CHARACTERS OF PUS.—The pus yielded by a healthy but not aseptic granulation-tissue was formerly spoken of as ‘healthy’ pus—*pus bonum et laudabile*. Its appearance indicated a local or general change for the better. Such pus is yellowish-white in colour, opaque, creamy in consistence, and neutral or alkaline in reaction, with sp. gr. 1030–1040. It has a faint sickly odour and does not putrefy readily. With an equal quantity of liquor potassæ it forms a gelatinous mass. On standing it separates into a deep sediment and a clear supernatant fluid (*liquor puris*). The latter is highly albuminous, does not coagulate spontaneously, and contains salts in about the same proportion as plasma, along with a certain quantity of peptones. The deposit consists of leucocytes, for the most part dead and fattily degenerated, with the addition of a varying number of red corpuscles which may render the pus *sanious* or give it merely a saffron or orange tinge from the presence of hæmoglobin. It also contains fine shreds of tissue, fatty and albuminous particles, and cocci, which are distinguished by their grouping and by appropriate methods of staining. The commonest departure from this type is that the pus becomes thin and acid, irritating to the tissues, and liable to rapid putrefaction (*ichor*). It sometimes has a very offensive odour, especially when the abscess has formed near the alimentary tract or vagina, owing to the presence of the *Bacillus coli*; but offensive pus in other situations, e.g. in the thigh, may be met with, and is then due to the action of the *Bacillus pyogenes fetidus*. Bluish or greenish pus is very rare and is due to the *Bacillus pyocyaneus*.

SYMPTOMS.—A fairly circumscribed area of the skin is found to be swollen, more or less red, hot, painful and tender; and these signs are all most marked towards the centre. Pressure with the finger tip or nail produces pitting owing to the presence of œdema. Fluctuation can be obtained by the method given below. As the abscess advances the centre of the affected area becomes more prominent, and fluctuation becomes more distinct: the red colour deepens into purple or blue, and the skin becomes progressively thinner. This sequence of events is known as the ‘pointing’ of an abscess. Finally the epidermis gives way and the contents of the abscess are discharged.

The method of obtaining fluctuation is as follows: the pulps of three fingers, if possible of each hand, are placed upon the swelling and kept as far from each other as the size of it permits. The fingers of one hand remain resting lightly on the surface, while those of the other hand gently compress the swelling. The fluid is thus driven beneath the resting fingers and raises them up. Experience is necessary to avoid mistakes: if the fingers are too close together, fat or œdema may give a sensation of fluctuation. It is never advisable to try to obtain fluctuation across a muscular belly, but always longitudinally in the direction of the fibres of any underlying muscle.

Constitutional symptoms vary greatly in nature and severity. Pyrexia varying from 100° to 104° F. is usually present, being generally proportionate to the acuteness of the inflammation, the amount of tension existing, the size of the abscess and its situation, absorption being more free from some parts, e.g.

knee, than from others. Not uncommonly the onset of suppuration is marked by a rigor, but 'chills' are more frequent: the rigor may be repeated more than once without any sign of pyæmia appearing. As the pus becomes surrounded by a wall of granulation-tissue the temperature falls; and it may even reach normal if the abscess remains long unopened.

The lymphatic glands above an abscess are often swollen and tender; lymphangitis occurs much less commonly.

Special symptoms arise in connection with pressure upon, or extension of œdema to, important parts.

In sub-fascial abscesses, e.g. in connection with acute necrosis of bone, the part swells diffusely and does not at first pit. If there be difficulty in localising the pus, it is advisable to look for the point of maximum swelling, and of maximum tenderness, and for any appearance of redness or œdema of the skin.

The discussion of abscesses occurring in special organs will be found under the heading of the respective parts involved.

DIAGNOSIS.—Diagnosis is usually easy. If an acute localised inflammation persists four or five days with the signs above mentioned well marked, pus is almost certainly present, even though fluctuation cannot be obtained. Some rapidly growing sarcomata have given rise to all the physical signs and symptoms of inflammation and have seemed to fluctuate: such cases are, however, very exceptional. Exploration may be necessary to determine the presence or absence of pus. The sacs of aneurysms sometimes suppurate, usually owing to some injury—either accidental or in the course of treatment. A history pointing to the existence of aneurysm is all-important in such cases. See ANEURYSM.

TERMINATION.—An acute abscess usually bursts through the surface of the skin and then heals. If it discharge on to a mucous surface, draining is often imperfect and serious septic absorption may occur. If it rupture on to a serous or synovial surface, diffuse inflammation of the cavity may be the result. Far more commonly, however, this last occurrence is prevented by the formation of adhesions round about the abscess before it bursts, so that in many cases, e.g. in the peritoneum, the pus crosses the cavity in safety and makes its way to the surface of the skin or into some hollow viscus. Absorption of an acute abscess is very rare: rarely, too, it becomes chronic. Delayed healing with the formation of an ulcer, sinus, or fistula is a common termination.

TREATMENT.—At first the ordinary treatment of inflammation (see INFLAMMATION) should be employed. As soon as pus is found or its existence strongly suspected, an incision should be made with a straight knife—not with a curved Syme's knife which inflicts the maximum of pain and makes relatively the smallest opening into the cavity. Except where it is important not to leave a scar, the opening should be free enough to drain, unaided, a small abscess, and to admit a finger to explore a large one. The finger should carefully seek out all 'pockets' and small-mouthed recesses, which should be well opened up into the main cavity. Formerly the formation of a dependent opening was considered necessary, but now it is more important to keep the opening away from any point from which infection is likely to occur. If this is avoided the discharge soon becomes thin and drains 'up hill' readily. Still, drainage should be thorough, and

in septic cases it may be necessary to make many incisions at various points. A wide incision or an 'anchored' tube, with a moist compressive dressing or fomentation, is the best means of draining away pus. The outer end of the tube should be kept flush with the surface of the skin, the deep end being shortened as necessary. When the discharge has fallen to a small amount, the tube should be removed experimentally, careful watch being kept for local discomfort or rise of temperature. Next day, or the day after, a probe should be passed along the track of the tube to see if pus has collected, and the tube replaced if necessary.

When it is wished to reach pus at some depth through a small wound, the skin and fascia may be cut through and a pair of closed sinus-forceps pushed in the direction of the cavity until resistance ceases; the forceps are then withdrawn with the blades open, a probe having been previously introduced along them as a guide (Hilton). Small vessels thus escape injury. But in cases of real danger to vessels or other important structures the wound should be large enough to allow the operator to work with a knife under guidance of sight.

B. Chronic Abscess.—**DEFINITION.**—A circumscribed collection of puriform fluid developing slowly with little or no sign of inflammation and with slight, if any, fever.

ÆTIOLOGY.—Although a very few acute abscesses quiet down and run a chronic course, and a few abscesses, due to staphylococci and other germs, run a chronic course throughout, the term '*chronic abscess*' practically means a softened 'tubercular focus.' The exciting cause is therefore the *Bacillus tuberculosis*: the proofs of this are absolute. Pre-disposing causes are an inherited tendency to tuberculosis; certain general depressing influences—such as faulty hygienic conditions, measles, and diabetes mellitus—which favour infection by this organism; and slight injuries which act similarly but locally.

MODE OF ENTRY AND OF SPREAD.—The tubercle-bacillus may gain access to the tissues (1) by inoculation upon a scratch or larger lesion of skin or mucosa (e. g. tonsil); (2) perhaps by passage through the uninjured respiratory or intestinal mucous membrane in company with other particles.

The bacilli may give rise to a tubercular ulcer at the point of inoculation; but it is common to find that before they have been able to cause superficial mischief they have been taken up by the lymph-stream and carried to the nearest glands, where they have been deposited. In such a case no history or sign of the lesion by which they entered can be discovered, as is frequently noted when the cervical or the mediastinal glands are the seat of infection. From the gland first reached they may be carried by lymphatics to many others. Less commonly the bacilli are arrested in the lymphatics leading from the point of entry to the glands. From any tubercular focus extension by the blood-path may occur: usually a tubercular phlebitis is excited, and the inflammatory deposit in the vessel-wall softens and breaks down, thus discharging bacilli into the vein. More rarely an artery is affected. It is conceivable that leucocytes may carry bacilli in small numbers into the circulation. On first entering the venous circulation the bacilli are carried to the lungs, and may even pass through the pulmonary capillaries and reach other parts of the body, where they are deposited. If they here encounter conditions un-

favourable to their growth, they will be destroyed or eliminated: but if they find a favourable soil they multiply and give rise to tubercular foci. Tuberculosis of bones, joints, testicles, kidneys, and other parts, removed from direct infection or infection through lymphatics, is brought about in this manner.

RESULT OF LOCAL INFECTION.—A tubercular infiltration slowly develops in which 'giant-cell systems' are usually discoverable. Fatty degeneration and softening of the inflammatory tissue soon take place (see CASEATION). Upon a free surface the result of this process is ulceration; but in the subcutaneous tissue or any deeper part, such softening gives rise to a 'chronic abscess.' Why softening occurs in some cases of tubercular infiltration and not in others is unknown.

ANATOMY OF CHRONIC ABSCESS.—If a small subcutaneous abscess be cut out along with its surrounding fat, it will present on section a central cavity containing puriform material limited by walls which are ragged and irregular. To the naked eye the wall seems to consist of granulation-tissue which becomes opaque and yellowish towards the cavity, and more or less fibrous towards the surrounding fat. Here and there between the fat-bubbles small foci of granulation-tissue may be seen. Starting from the periphery the microscope shows round-celled infiltration among the fat with more or less tendency to the formation of a fibrous capsule. Passing inwards the round-celled infiltration becomes denser, and soon 'giant-cell systems' appear embedded in it in greater or less numbers. Still nearer to the centre patches of fatty degeneration are noticed, and this soon becomes uniform and universal as the cavity is approached. No structure is seen—only fatty granules which seem to be dropping into the cavity when the lining layer is reached. Outlying nodules of granulation-tissue show similar tubercular structure. They are due to the passage of bacilli along a lymph-path from the primary focus, and exhibit the same series of changes. They gradually enlarge and ultimately coalesce with the primary focus. Spreading in this way and exercising harmful pressure on the vessels supplying the surface, a chronic abscess renders the skin over it thin and purple. Finally this gives way and the contents are more or less completely discharged. When a tubercular focus in bone softens—e.g. in a lumbar vertebral body—the 'pus' slowly makes its way to the surface of the bone. Here it may form a collection under the periosteum and extend along the line of least resistance. Thus it may pass back into the loin along the lumbar vessels (lumbar abscess), or escape from the bone into a process of origin of the psoas muscle on one or both sides. In the latter case, the pressure of the increasing exudation causes atrophy of the muscle-fibres, while the fibrous tissue is thickened and forms a dense sheath for the pus. The cavity thus formed becomes lined by a layer of tubercular granulation-tissue, poorly supplied with vessels and very loosely attached. Vessels of considerable size and nerves may persist, stretching across the cavity as isolated strands. Such an abscess not uncommonly raises the iliac fascia and fills the iliac fossa (*iliac abscess*) before it passes beneath Poupart's ligament (*psoas abscess*) to pass down the thigh along the profunda artery or back along the internal circumflex vessels. These are types of chronic abscesses. In all, the walls are tuberculous, and until this lining is removed or cast off, healing will not occur.

CHARACTERS OF THE 'PUS.'—The fluid in these abscesses is thin and watery. It often contains small yellowish-white masses like curds, and sometimes small calcareous or bony particles. Under the microscope fatty granules and degenerated crumbling leucocytes are seen. Hardly any normal white corpuscles are to be found.

SEATS.—The commonest seats of chronic abscess are the subcutaneous tissue, especially in children; the lymphatic glands; cancellous bones such as the vertebrae, the epiphyses, and the ribs; the synovial membranes of joints; and the epididymis.

SYMPTOMS.—Symptoms are often absent until a swelling is accidentally noticed. The swelling is smooth and rounded; it is painless, and fluctuation is readily obtained. The skin over it is not tender, red, hot, or cedematous until the abscess is on the point of bursting. There is often no thickening at its margin, but sometimes a ring of infiltration is felt. When the lesion originates in a bone, the base of the abscess is naturally fixed. When a collection of tuberculous matter reaches the surface from the thoracic or abdominal cavity, the swelling is not uncommonly stated by patients to have appeared suddenly. Coughing causes such an abscess to swell up and to impart an impulse to the hand laid upon it; but this phenomenon does not occur invariably. The erectors spinæ, being expiratory muscles, seem to yield an impulse on coughing.

More than one chronic abscess may be met with in the same patient: sometimes a large number may co-exist. Little or no fever accompanies the process. Sometimes an abscess may press upon a nerve and cause pain—which may even be severe; but pain is usually a symptom of the disease in the bone or joint whence the abscess springs. The symptoms of such disease are superadded to those of the abscess, and must be carefully investigated in order to determine the source of the 'pus.'

The patients are usually children or young adults, though no age is exempt. A history or physical evidence of tuberculosis is often obtainable. The general condition may leave nothing to be desired, but often it is poor. The presence of considerable fever with an unopened or aseptically opened chronic abscess indicates the existence of some complication, perhaps general tuberculosis.

COURSE OF A CHRONIC ABSCESS.—When not interfered with a chronic abscess may occasionally become absorbed: usually it enlarges more or less rapidly, and may reach enormous dimensions. Ultimately the skin over it at some spot becomes thin, red, or bluish in colour, and eventually gives way. The contents escape imperfectly; infection of the cavity by pyogenic and septic germs occurs; and the patient may die of acute septicæmia. In other cases hectic fever ensues, and in spite of the establishment of counter-openings, the abscess burrows and appears at fresh spots. Amyloid disease of viscera follows, and, if recovery occurs, it is with a ruined constitution. Such is the course of a large spinal abscess untreated or treated unsuccessfully as regards asepsis. Even when such an abscess heals, tuberculous tissue locked up in the deep scar often infects the surrounding parts afresh, and recurrence (*residual abscess*) sooner or later occurs. Smaller abscesses, and those not connected with bone, heal more readily even under such conditions.

DIAGNOSIS.—Effusions of blood, serous cysts, herniæ, fatty tumours and soft sarcomata, and some-

times firmer, deeply seated, malignant growths have all to be carefully differentiated from Chronic Abscess. Exploratory puncture or operation must be undertaken as a last resort. The diagnosis of 'tumour' should not be made until inflammation has been eliminated.

Sometimes in cases of spinal disease with psoas abscess the hip-joint is persistently flexed, and pain is caused by any attempt to extend it; probably, the psoas-sheath is filled unusually tightly and nerves are pressed upon. Disease of the hip-joint, which may cause an abscess above Poupart's ligament, is thus simulated, but may be eliminated by noting that the outline of the trochanter is in no way blurred, and that movements of the hip other than extension are free and painless. Signs of spinal disease are usually, but not always, discoverable. The impulse on coughing which is communicated to a collection of fluid in communication with the thoracic or abdominal cavity has been already alluded to.

PROGNOSIS.—The prognosis will vary with the number and size of the abscesses, their source, the age, health, and means of the patient, and the condition of sepsis or asepsis existing in the cavity. An origin from bone or joint is more serious than from glands and soft parts. The older the patient, after childhood, the worse is the prognosis.

TREATMENT.—The following are the chief therapeutical indications. Disease of spine or joint must be carefully attended to. Everything possible should be done to secure fresh air and sunlight, and good nourishing food for the patient. Cod-liver oil is generally valuable in these cases, and the use of an antiseptic internally, such as creasote increased drop by drop to large doses, is recommended by some authorities. With regard to the abscess, whatever operative treatment is adopted should be conducted with scrupulous attention to asepsis.

1. Aspiration, generally repeated more than once, has occasionally been followed by drying up of the abscess. Usually, however, it fails, and may result in the formation of a fistula or give origin to a septic infection of the cavity. Further, even when it succeeds, it leaves all the tuberculous tissue behind. Sometimes aspiration has been combined with irrigation with some antiseptic solution, or with the introduction of iodoform. The needle should always be introduced through a considerable thickness of tissue—not through the thinnest point: in the latter case infection of the track and the formation of a sinus will inevitably result.

2. Excision of the abscess with some healthy tissue around it is the ideal treatment. It can be practised in subcutaneous and glandular foci, and in abscesses connected with some bones and joints—the chisel or gouge being used to remove infected portions of the bone. The wound is to be completely closed and allowed to heal like any other aseptic wound.

3. When excision is impossible, the cavity should be laid open fully; as much as possible of the wall should be excised, and the rest should be carefully scraped with a spoon and rubbed with a dab, after which pure carbolic acid may be lightly applied, followed by a little iodoform. The wound should be closed without drainage; but if this cannot be done it should be plugged with iodoform-gauze.

4. In psoas and similar abscesses, practically no excision can be done. Incisions must then be

made in the loin, groin, and thigh, as may be convenient, in order to allow the lining membrane to be scraped away from the whole cavity, which is kept flushed meanwhile with saline solution. As a rule, even in the lumbar operation for lumbar disease, it is impossible to find the track by which the cavity communicates with the diseased vertebra, but if this can be found, there need be no hesitation in scraping it also. Iodoform-emulsion should be introduced into the cavity and the wounds closed. If after three or four days the cavity is distended with fluid, it should be aspirated. The fluid should somewhat resemble honey and smell strongly of iodoform. If left to accumulate it sometimes bursts through the stitches.

5. When the cavity is septic, too free drainage cannot be provided. Plugging from the very bottom with iodoform-gauze is best. Failing this, large tubes may be introduced through suitable openings, and irrigation practised with either sterile saline solution or iodine-lotion (one drachm of the tincture to one pint of water).

The tubes should not be abandoned nor smaller sizes substituted until it is certain that they have no more work to do. The openings must be kept dilated.

Bad cases of this kind require the exercise of the greatest patience. Good hygiene and careful feeding are very important; also fixation of the spine or any joint which may be affected. The discharge should be regular in amount, not varying in quantity from day to day. Rise of temperature may be due to an unusual amount of septic absorption, especially after rough treatment of the granulations; to retention of discharge or formation of some fresh pocket; to general tuberculosis; or to some accidental cause. It is an indication for a careful examination of the patient with a view to removal of the faulty condition. No avoidable operation should be done until the cause of the fever is determined.

C. Acute Diffuse Suppuration.—The subcutaneous tissue, especially that of the upper limb, is the most common seat of acute diffuse suppuration.

ÆTIOLOGY.—The principal exciting causes of this condition are: (1) *Extravasated urine*, especially if it be septic; (2) the *Streptococcus pyogenes*; (3) the virus introduced in *dissection-wounds*. This last is probably also due to the streptococcus, which is the common cause of ordinary diffuse cellulitis. The lesion of the surface, through which infection occurs, is generally easy to discover, but a few cases appear to arise spontaneously; these may possibly be due to organisms which have entered at distant points of injury or have passed through uninjured mucous membranes, and have been deposited in the infected area by the blood-stream. Slight wounds of the hands, especially those occurring in dissectors, surgeons, butchers, fishermen, &c., are specially liable to be followed by this complication; so also are lesions of the tonsils and of the cervix uteri, and all infected wounds which pass through the deep fasciæ, e.g. that of the scalp.

MORBID ANATOMY.—The affected part is diffusely swollen; the epidermis is often raised into bullæ here and there by effusion of fluid beneath it, and may separate, leaving grey or yellow patches of denuded corium exposed. Irregular openings in the skin may exist, through which pus escapes and sloughs can be seen. The fat is opaque and of a pale-yellow colour. The structure of the tissues is

rendered cloudy and indistinct owing to infiltration with a turbid fluid, which here and there forms collections of thin pus. Pieces of fascia and connective tissue, which have undergone necrosis and separation, are visible as dirty yellowish masses, resembling sodden wash-leather. The process may be confined to a comparatively small part, or it may involve a whole limb or even more. It may remain superficial to the deep fascia, or extend deeply between the muscles, leading to sloughing of tendons or even of the muscular substance. In rare cases it may lead to suppuration of joints, or necrosis of bones. The veins contain softening thrombi, and portions of such clots may be carried away by the blood-stream and give rise to secondary pyæmic foci. Streptococci are plentiful in the pus, the lymph-paths and the softening blood-clot. The disease may be set up at a distance from the point of infection: thus the axilla may be the seat of diffuse suppuration as the result of a pricked finger.

SYMPTOMS.—The onset is marked by all the usual signs of inflammation, which extend over a wider area than in cases of simple abscess and show no tendency to circumscription. The fever is more severe, and the occurrence of one or more rigors is not uncommon. As the disease progresses the red colour of the skin becomes deeper at certain spots, and a finger passed over the surface tends to sink in a little at these points. This 'bogginess' or localised softening is the best sign of the presence of collections of pus. Fluctuation may be nowhere distinct until great damage has been done, or it may seem present everywhere on account of the great oedema. As the process extends, fresh spots of softening appear; then the skin gives way and pus escapes. Sloughs protrude from the openings, which rapidly enlarge; and extensive tracts of skin are undermined and may undergo necrosis. Fever, suffering, and repeated incisions tell severely on the patient; and in bad cases septicæmia or pyæmia may ensue and prove fatal, or a condition of hectic fever may be established and threaten a fatal termination. The sloughs are slow in separating, and if important tendons are involved, the question will arise whether the part, even if it can be saved, will be subsequently of any value, since the process of healing necessarily results in a matting together of the parts by a mass of dense fibrous tissue.

DIAGNOSIS.—In cases of acute diffuse inflammation of a part it is often impossible to recognise at once the existence of suppuration (*see* CELLULITIS). In such instances exploratory incisions may be necessary. Thus in axillary and cervical cellulitis (*Angina Ludovici*), and in other cases of deeply seated inflammation, the local swelling and the fever not only justify but necessitate incision, since the patient may die before fluctuation is obtained. No distinction can be maintained between acute diffuse suppuration and the condition known as cellulotaneous erysipelas.

TREATMENT.—It is advisable to immediately disinfect the point of inoculation, when this is distinguishable, with pure carbolic acid, and to adopt the ordinary methods of treating inflammation. Elevation of the affected part is especially necessary. If these measures prove ineffectual, the part must be freely incised, but the deep fascia should not be opened up, unless the disease has already invaded parts lying beneath it. All bleeding should be care-

fully arrested. Sloughs must be removed and collections of pus drained. Pure carbolic acid is to be applied to the dried exposed surfaces. The wounds are then plugged lightly with iodoform-gauze, and fomentations are applied when all danger of bleeding has ceased. It is useful in freely suppurating cases to keep the limb in a warm bath of boric-acid lotion for some hours every day. When granulation occurs, movements of all damaged parts should be regularly practised. Careful feeding is most important, especially as the pyrexia abates, and a moderate amount of stimulants may be beneficial. When a part is hopelessly injured or life is threatened by prolonged suppuration, resort must be had to amputation or excision of the seat of disease.

STANLEY BOYD.

ABSCESS, Subdiaphragmatic.—**SYNON.** : *Subphrenic Abscess.* *See* SUBDIAPHRAGMATIC ABSCESS.

ABSINTHISM.—**DEFINITION.**—The condition induced by an excessive consumption of absinthe.

From the mode in which absinthe is taken, we should expect that the symptoms induced by its excessive consumption would be generally obscured by, and intermixed with, those of alcohol (*see* ALCOHOLISM). That it has a special effect on the organism, and that this may be diagnosed from alcoholism, is, however, generally recognised. In persistent absinthe-drinkers, vertigo and epileptiform convulsions are marked symptoms, and come on much earlier than when alcohol, in other forms, is habitually drunk. Hallucinations occur also without any other symptom of delirium tremens; and, when tremors coexist, these are limited more particularly to the muscles of the arms, hands, and shoulders, since absinthe acts chiefly on the cervical portion of the spinal cord.

JOHN CURNOW.

ABSORBENT AGENTS.—In *surgery*, absorbents are substances used to absorb fluids, as cotton-wool, lint, or compressed moss; in *medicine*, the term is made use of to designate remedies, such as the preparations of mercury and iodine, which are believed to possess the property of promoting the absorption of morbid products.

ABSORBENT VESSELS and GLANDS, Diseases of.—*See* LYMPHATIC SYSTEM, Diseases of; BRONCHIAL GLANDS, Diseases of; and MES-ENTERIC GLANDS, Diseases of.

ACANTHOSIS.—This term, originally used by Auspitz to signify diseases of the skin produced by anomalies in the spinous or prickle-cell layer of the epidermis, has been adopted more recently by Unna to specify proliferation of the prickle-cell layer as the result of mitotic division of its cells.

JAMES GALLOWAY.

ACANTHOSIS NIGRICANS.—This rare affection of the skin was first definitely recognised in 1890.

Patients affected by this disease present an exceedingly characteristic appearance. When the disease is fully developed certain regions of the body show an increase of pigmentation, giving rise to a brownish or even black colour. At the same time, the surface of the skin becomes rough, and this roughness may be so exaggerated as to give rise to papillary excrescences as large as, or even larger than, ordinary warts. The axillæ, the genito-crural region, the neck, the flexor surfaces of the joints, the face and mammary regions, are usually affected symmetrically.

In addition to these areas, any part of the surface of the body may show increase of pigmentation, and frequently, instead of actual warty or papillary excrescences on the surface, an exaggeration of the normal lines of the skin is noted. The mucous membranes may also be affected. See ADDISON'S DISEASE.

Histological examination of the skin shows that the main lesions occur in the epidermis. There is increase in the thickness of the prickly-cell layers of the epidermis—the condition which gives the name to this disease—the stratum granulosum is retained intact, and the horny layer is hypertrophied. In consequence of this over-growth of the epidermis, the interpapillary processes are elongated and hypertrophied, and coincidentally the papillæ themselves are elongated or irregularly enlarged. The pigmentation which gives such a striking colour to the patient consists of an exaggeration of the normal pigment, and its granules are contained in the basal and one or two of the overlying layers of the stratum mucosum.

A large number of the described cases of the disease have been associated with various forms of abdominal tumour, the majority of which have been of malignant character. Beyond this very striking coincidence, no suggestion has yet been obtained as to the relationships of the disease. It may commence at any period of life, but more usually develops in adults. Cases are, however, recorded commencing at two, three, and eleven years of age. The duration of the malady is indefinite, and the course is that of a gradually increasing dystrophy of the skin. If a malignant tumour is associated with the disease the prognosis depends upon the character of the growth.

TREATMENT appears to have no effect whatever in arresting the disease. Care must be taken to observe *special cleanliness* of the skin, especially in the groins, axillæ, and similar regions. Occasionally anti-pruritic lotions may be required. It is sometimes necessary to remove the papillomata if they become troublesome on account of their situation or their size, and this may be done by excision or by the cautery.

JAMES GALLOWAY.

ACARUS.—*Acar*i or *mites* constitute the tracheal order of the class *Arachnida*, several species of which are parasitic. The *Acarus scabiei* or *Sarcoptes hominis*, and the *Acarus folliculorum*, or more properly the *Demodex folliculorum* or *Steatozon folliculorum*, are the only human parasites belonging to this family.

DESCRIPTION.—1. The *Acarus Scabiei* is a small roundish animal, just visible to the naked eye. Examined under the microscope it is seen to be flattened, and to resemble a tortoise in shape; when fully developed it has eight legs. Over its body are scattered a few setæ, and on the dorsal surface are several rows of triangular spines (see fig. 1). The female is larger than the male, and is provided with terminal suckers on the four anterior legs, while setæ occupy a similar position on the posterior ones: in the male, however, the two posterior median legs have suckers like those on its fore limbs. The *young acarus* has only six legs, the two hindmost ones, which are distinctive of the sex, being wanting; it acquires these after shedding its skin two or three times. The male *acarus* lives near the surface of the skin, while the female burrows within the middle horny layer, and deposits

from ten to fifteen eggs in the cuniculus or burrow; these eggs hatch in about a fortnight. The young *acar*i escape from the burrow, but the parent does not leave it and dies when she has finished laying eggs. The *Acarus scabiei* is the cause of the skin-affection termed *Scabies* or *Itch*. See SCABIES.

FIG. 1.—*Acarus scabiei*. 1, female; 2, male; 3, ovum; 4, anterior legs terminating in stalked suckers (s.s.); a.l., posterior legs terminating in baristles; i.p.l., posterior median legs of male terminating in stalked suckers; d.s., dorsal spines; s., setæ; s.p., support for penis. $\times 90$. (From 'Green's Pathology'.)

2. The *Acarus folliculorum* is a very minute parasite found in the sebaceous glands of the face, ear, and trunk. In this animal the head is continuous with the thorax, and to the latter are attached eight very short legs, each armed with three strong claws. On each side of the head are short jointed pedopalmi. The abdomen varies in length from twice to three or four times that of the thorax; it is pointed at its distal extremity. The presence of this parasite in the skin is unimportant. It is occasionally associated with a peculiar discoloration.

ROBERT LIVEING.

ACCOMMODATION, Disorders of.—See VISION, Disorders of.

ACEPHALOCYST (ἀ, priv.; κεφαλή, a head; and κύστις, a bag).—A hydatid cyst without any scolices in its interior. See ENTOZOA—Hydatids.

ACHOLIA (ἀ, priv.; and χολή, bile).—Absence or deficiency of bile. See BILE, Disorders of.

ACHONDROPLASIA (ἀ, priv.; χόνδρος, cartilage; πλάσσω, I form).—SYNON.: *Fætal Rickets*; *Fætal Crétinism*; *Chondrodystrophia fætal*.

DEFINITION.—A disease of fœtal life, causing stunted growth of the limbs and consequent dwarfing.

PATHOLOGY.—Longitudinal growth ceases in the diaphyses of certain bones, which develop from cartilage and ossify early: those principally affected

are the long bones of the limbs, the ribs, the innominate bones, and those forming the base of the skull. The cause of the condition is unknown. It is probably unconnected with any failure of thyroid-secretion or with ordinary rickets. The morbid process is confined to the early months (3rd to 6th) of foetal life; it appears to consist in a defective formation of the cartilaginous precursor of the bone, and is no longer active at birth. Abortion frequently occurs when the foetus suffers from this disease, but in those which survive the general health and intelligence are good.

CLINICAL CHARACTERS.—The arms and legs are abnormally short: the fingers may not reach below the crest of the ilium, and the legs may be so stunted that the patient sits down on the ground and rises again without apparent effort. The epiphyses are enlarged, the long bones curved and the fingers divergent, the angle between the middle and ring fingers being specially marked. The bridge of the nose is depressed and the base of the skull generally contracted, so that the cranium above appears unduly large. The body is of normal length, but the total height of an achondroplastic adult may be little over four feet. The gait is waddling, with lumbar lordosis; and the patients are helpless owing to the shortness of the arms, which causes inability to wash, dress, and attend to themselves. The disease is occasionally confounded with cretinism, but the deformity is really quite different, and the intelligence unaffected.

W. CECIL BOSANQUET.

ACHOR } ($\acute{\alpha}\chi\acute{\omega\rho}$, scurf or dandruff,
ACHORION } $\acute{\alpha}\chi\upsilon\rho\acute{\omega}\nu$, chaff).

The word Achor is now almost obsolete; it was formerly applied to a small follicular pustule of the scalp.

Achorion is the term assigned to one of the three principal dermatophytes or epiphytes of the skin. It constitutes the crust of Favus and belongs to the group of fungoid plants denominated *Oidium*.

As *Achorion* was the first discovered of the cutaneous epiphytes, in compliment to one of its early observers, Schönlein, it has been named *Achorion Schönleinitii*. It is the agent of contagion in favus (see FAVUS), but it is also found in *Onychomycosis*, a condition in which the matrix of the nail is invaded.

JOHN HAROLD.

ACHROMA ($\acute{\alpha}$, priv.; and $\chi\rho\acute{\omega}\mu\alpha$, colour).—Absence of colour; an achromatous or colourless state of a usually coloured tissue, due to absence of pigment. In reference to the skin achroma is synonymous with leucoderma, albinism, and aliphsis. See PIGMENTARY DISEASES OF THE SKIN.

ACHROMATOPSIA ($\acute{\alpha}$, priv.; $\chi\rho\acute{\omega}\mu\alpha$, colour; and $\acute{\omega}\psi$, sight).—More or less complete inability to distinguish colours from each other. See VISION, Disorders of.

ACIDITY.—The term acidity is used in medicine (1) in the ordinary sense to denote that a fluid possesses an acid reaction; (2) to indicate hyper-acidity, as in the expression 'acidity of the stomach;' or (3) to mean diminished alkalinity although the reaction may not become acid, as in the phrase 'acidity of the blood.'

Most of the fluids of the body give a variable result with different indicators, because their

reaction is due to weak acids such as carbonic acid, or to acid salts. Thus, saliva is alkaline to litmus but usually acid to phenol-phthalein. This varying reaction is capable of yielding a certain amount of information as to the character of the dissolved salts causing the reaction. By the use of very stable indicators it may also be determined whether an acid reaction is due to a free acid or to an acid salt; and also within certain limits whether the reaction is due to a strong (mineral) acid or to a weak (organic) acid. It is on this principle that all the many 'colour-reactions' for determining the presence or absence of free hydrochloric acid in the stomach are based.

Even those fluids in the body which are commonly regarded as alkaline, because of their giving an alkaline reaction with organic indicators such as litmus, contain acid salts such as sodium bicarbonate and di-sodic phosphate in addition to excess of carbonic acid, and hence in this sense may be spoken of as possessing acidity. In such fluids the acidity, as well as the alkalinity, can accordingly be determined and its variation under morbid conditions studied; this has been done particularly in the case of the blood.

1. ACIDITY OF THE BLOOD.—The acidity of the blood becomes increased in the sense defined above when there is either an increased amount of incompletely oxidised organic substances of an acid character formed by the tissues, or a less perfect elimination of such substances by the kidneys. Accordingly, a marked increase of acidity is found in fever and in diabetic coma; for example, Kraus states that the acidity of normal blood is equivalent to (i.e. capable of neutralising) 0.162 to 0.232 grm. of sodium hydrate per 100 grm. of blood, while under febrile conditions it may be increased to 0.272 grm. and in diabetic coma to 0.347 grm. Other observers have even detected an acid reaction of the blood to litmus in diabetic coma and in the cold stage of cholera. Increased acidity of the blood is also found in gouty and rheumatoid conditions, and occasionally in eczema and other skin-affections.

2. ACIDITY OF THE URINE.—The urine of persons fed upon a mixed diet, when collected over a period of twenty-four hours, has normally an acid reaction to litmus, but when tested with those more stable indicators which are only changed by free acid (such as methyl-orange or tropaeolin), no acid reaction is shown. This demonstrates that the acidity of urine is due to acid salts, and quantitative estimation further proves that the acidity and degree of acidity to such indicators as litmus is due to a variable mixture of mono-sodium and di-sodium phosphates. The former of these salts has an acid reaction to litmus, and the latter an alkaline one, and the reaction of any variable mixture of the two, such as is excreted by the kidneys, depends in kind and amount upon the total quantity and the ratio of the two salts in the urine.

Since one of the most important functions of the kidneys is to maintain a constant degree of alkalinity of the blood, it follows that the degree of acidity or alkalinity of the urine must vary directly with that of the blood, and indeed can be taken as an index of the condition of that fluid as to reaction. An increased alkalinity of the blood from any cause leads to the excretion of a less acid, or it may be an alkaline, urine, in order that the alkalinity of the blood may be reduced to normal. As an example

of this may be taken the so-called 'alkaline tide' met with in the urine during the first period of digestion after a meal. Here the secretion of acid gastric juice raises the alkalinity of the blood, and accordingly the kidneys excrete more alkali from it, so giving rise to a more feebly acid or it may be alkaline urine. At a later period, the alkaline juices poured into the intestine are separated from the circulating blood while the separation of hydrochloric acid ceases. Accordingly the alkalinity of the blood falls below normal and the kidneys secrete a hyper-acid urine in order to compensate. The character of the food also tends to alter the degree of alkalinity of the blood, and this tendency is compensated by corresponding variations in the urinary excretion. It is for this reason that the urine of herbivorous animals is normally alkaline, for during inanition their urine becomes acid. So also in man the reaction of the urine can be made alkaline, or its acidity reduced, by a diet of green vegetables. The alkali in such green food is present in the form of alkaline salts of organic acids, and when these acids undergo oxidation in the body, the bases become combined as carbonates which raise, or tend to raise, the alkalinity of the blood. This may be shown by administration of such salts as sodium or potassium citrate, tartrate, or acetate, or of the carbonates or bicarbonates of the alkalis. By such means the alkalinity of the blood is increased, and the acidity of the urine diminished or even replaced by an alkaline reaction.

An excessive meat-diet, on the other hand, increases the acidity of both blood and urine by giving rise to incompletely oxidised organic acids, such as uric acid, which cannot be excreted as such, and which therefore combine with a certain amount of the alkali of the blood, so reducing the degree of alkalinity. The sulphur and phosphorus of proteid are also oxidised in the body to sulphates and phosphates respectively, and this removal of alkalis in combination also tends to diminish the alkalinity of the blood. This process may be carried so far that the alkali is reduced to the level at which it no longer reacts readily with weak organic acids to form salts, and in the case of uric acid, which is almost insoluble in the free form, this may lead to its deposition in the tissues or in the urine. In this way either a uric acid diathesis, gout, or urinary calculi may originate. Since the primary cause is incomplete proteid-oxidation, the first thing indicated is a diminution of the patient's 'luxus-supply' of proteid, along with exercise, and a liberal diet of green vegetable food. These measures should be accompanied by the moderate use of alkalis until the crisis has been relieved. Since the lithium-salts of uric acid are the most soluble, lithium carbonate or lithium citrate is the form of alkali usually administered.

It is remarkable that in man and in the carnivora the acidity of the urine is not increased by the administration of even the mineral acids, except when the dose is so large as to lead to violent intoxication. Before acid intoxication takes place considerable amounts of the stronger mineral acids can be neutralised by the formation of ammonium salts, a corresponding decrease in the amount of urea excreted being observed. In herbivora, which are not subjected from the nature of their food to any danger of acid intoxication, it is interesting to observe that no such protective compensation takes place, and such animals quickly

succumb to comparatively small doses of mineral acids.

It is easy to deduce from the above statements that the *character of the food* is the primary factor in influencing the degree of alkalinity of the blood and the acidity of the urine. A diet too rich in proteid food, and especially animal proteid, leads to a diminished alkalinity of the blood, and the secretion of a hyperacid urine; while a diet rich in green vegetable matter has an opposite effect.

The reaction of the urine may change under pathological conditions from acid to alkaline, after it has been excreted by the kidney and before it is voided, because of bacterial fermentation set up in the urinary bladder or passages. Occasionally the alkalinity may be due to the secretion of alkaline mucus as a result of irritation of the mucous membrane. Fermentation is also often set up in cases of retention or incontinence of the urine, and the infection by the *Micrococcus ureæ* may occur either naturally by the urethra or as a result of careless catheterisation. The alkalinity is accompanied by cystitis which still further favours continued infection.

3. ACIDITY OF GASTRIC JUICE.—The gastric juice is the only fluid in the body which owes its acidity to free acid. It has been clearly shown that practically all the acidity of pure gastric juice unmixed with food is due to hydrochloric acid. During digestion of carbohydrates, lactic and other organic acids are formed by bacterial action, and under certain conditions favouring fermentation, such, for example, as chronic dyspepsia accompanied by distension of the stomach, the amount of organic acid formed may be very considerable and lead to gastric catarrh.

The percentage of hydrochloric acid varies considerably under morbid conditions. There is usually hyperacidity accompanying gastric ulcer, and this condition is also common in nervous dyspepsia. In the latter condition the acidity may be doubled, but the amount is variable, and there may often be either a normal amount or even sub-acidity. In both acute and chronic gastritis the amount of hydrochloric acid is subnormal and the organic acids are increased. In chronic catarrh, hydrochloric acid may be completely absent, and this is the usual condition in cancer of the stomach, where absence of the acid is an important, though by no means infallible, diagnostic sign (*see* STOMACH, New Growths of). Hydrochloric acid is stated also to be occasionally absent in hysteria and tabes dorsalis.

4. ACIDITY OF THE INTESTINE.—There is at the present time considerable difference of opinion as to the reaction of the intestine. The older view that the acidity of the chyme escaping from the stomach is neutralised, and the reaction changed to alkaline in the duodenum by the alkali of the digestive juices with which it is there mixed, has been controverted by recent observers. It is maintained by some of these authorities that the hydrochloric acid is never completely neutralised in the intestine, while others hold that the reaction of the intestine is normally acid owing to the presence of organic acids formed by bacterial action. According to the latter view bacterial action in the small intestine takes, under quite normal conditions, a considerable share in the digestion of carbohydrates.

The writer's own experiments have led him to regard the older view as to the reaction of the contents of the *small intestine* as more correct than

these modern statements. These experiments have shown that the degree of alkalinity of the intestine varies with the nature of the food, being decreased by a meat-diet, and increased by a carbohydrate-diet; further, that the alkalinity increases with the distance along the intestine, and that there is practically never an acid reaction to any indicator except phenol-phthalein in the lower portion. This last fact indicates that the alkalinity is due to acid salts of the alkalis, such as bicarbonates and bibasic phosphates. The reaction of the *large intestine* is variable, but most commonly acid, owing to the presence of organic acids formed as a result of bacterial action.

5. ACIDITY OF THE SWEAT.—The reaction of the sweat in man is normally slightly acid, even when it is collected from parts free of hair so as to be uncontaminated by sebaceous secretion. The acidity is due to volatile organic acids. In long-continued profuse sweating it is stated that the reaction may change to alkaline. *See* ALKALINITY.

BENJAMIN MOORE.

ACIDS.—**DEFINITION.**—Substances which combine with alkalis, and destroy their power of turning red litmus-paper blue. Most of the acids also redden blue litmus, and have a sour taste.

ENUMERATION.—Acids may be divided into *inorganic* or *mineral*, and *organic*. The mineral acids used in medicine are Boric, Carbonic, Chromic, Hydrochloric, Hydrobromic, Nitric, Nitro-hydrochloric, Phosphoric, Sulphuric, and Sulphurous acids. The organic acids thus employed include Acetic, Benzoic, Carbonic, Chrysophanic, Citric, Gallic, Hydrocyanic, Lactic, Oleic, Salicylic, Tannic, Tartaric, and Valerianic.

ACTION.—The stronger acids—sulphuric, nitric, hydrochloric, chromic, glacial acetic, and lactic acids—destroy animal tissues, and act as caustics when applied to the surface. When swallowed they produce the symptoms of irritant poisoning (*see* POISONS). An antidote for these poisons which is always at hand is carbonate of lime, in the form either of whiting, or of plaster chipped from the nearest wall. Other antidotes are alkaline carbonates and bicarbonates, milk, oil, and soap. Diluted acids, taken into the mouth, increase the secretion of saliva; and hydrochloric acid forms an important constituent of the gastric juice, without which digestion does not go on. When absorbed into the blood, dilute acids act on the heart generally, slowing its pulsations and reducing the temperature. They are excreted in the urine and milk.

USES.—Nitric acid is employed as a caustic application to piles, to poisoned wounds, and to spreading or unhealthy sores. Glacial acetic acid is used to destroy corns or warts. Diluted acetic acid or vinegar is applied as a lotion to relieve headache; to allay the itching of prurigo, lichen, and psoriasis; to check perspiration; and sometimes to hasten the appearance of exanthematous eruptions. Diluted acids, especially citric, tartaric, and hydrochloric, as well as acid tartrate of potassium, are administered in fevers as refrigerants, because they relieve the dryness of the mouth, and diminish the thirst by increasing the secretion of saliva, as well as lower the temperature and pulse-rate. Under the like circumstances, the organic acids, acetic, citric, and tartaric, when combined with alkaline carbonates in a state of effervescence or otherwise, form compounds which act on the skin and kidneys.

In febrile conditions, anæmia, and some forms of dyspepsia, the proportion of acid in the gastric juice is insufficient for the proper digestion of food, and the administration of dilute hydrochloric acid immediately before or after meals is useful both by aiding digestion and by preventing the formation of butyric and other acids, which give rise to sour eructations. Nitro-hydrochloric acid, before meals, is likewise beneficial in preventing acidity. It appears to have some action on the liver; and is used, both internally, and externally as a lotion or footbath, in jaundice and biliousness (*see* BALNEOLOGY). It generally relieves the frontal headache common in young women, which is felt just above the eyebrows, and not accompanied by constipation. Dilute acids, especially aromatic sulphuric acid, are useful in checking diarrhoea, colliquative sweats, hæmorrhages, and mucous discharges. By lessening the alkalinity of the urine, they tend to prevent the formation of phosphatic calculi, phosphoric, nitric, and lactic acids being most frequently employed for this purpose. Care must be exercised in their administration to nursing mothers, as they are excreted in the milk, and sometimes cause griping and diarrhoea in infants at the breast. Several acids have a special action of their own, and are considered under their respective groups, such as hydrocyanic and hydrobromic acids, which are sedative; boric and carbolic, antiseptic; chrysophanic, parasiticide; salicylic, antipruritic; gallic and tannic, astringent.

T. LAUDER BRUNTON.

ACIREALE, in Sicily.—Cold sulphur waters, and winter climatic health-resort. *See* MINERAL WATERS.

ACNE.—**SYNON.**: *Acne vulgaris*; *Acne adolescentium*; *Acne disseminata*; Fr. *Acmé*; *acné*; Ger. *Acne*.

DEFINITION.—A chronic disease of the skin, confined to the face, back, shoulders, and chest. The eruption is met with in young adults, and consists of pimples which are caused by an inflammation of the sebaceous glands and hair-follicles. The disease leaves small depressed scars.

ÆTIOLOGY.—The ætiology of acne is obscure. It is seldom met with before puberty, and is usually fully developed at about the age of eighteen or twenty, and then gradually disappears before the age of thirty. There are, however, many exceptions to this rule, especially in men, who are liable to a severe form of acne of the shoulders and back, which may continue until middle life. Acne appears to be equally common in males and females, and is especially met with in those who have what is called a slow circulation in the extremities—that is, who suffer from cold hands and feet, and perhaps chilblains. In accordance with this, the disease often improves, or even disappears, during warm summer weather, to return again in the following winter. The suppuration of the *comedones* is naturally attributed to pyogenic cocci (*see* ABSCESS), but these are often few in number and occasionally absent. Payne contrasts the pustules of acne with those of impetigo, in which cocci are plentiful. Unna attributes the disease to his *acne-bacillus*.

SYMPTOMS.—Common acne is a pimply eruption, met with chiefly on the face and shoulders, less often on the back and chest. Many of the pimples are of a pale colour with a small dark centre, and consist simply of follicles over-distended with sebum, the black centres marking the orifices of the follicles.

These pale little papules, called *comedones*, are apt to become red and inflamed, thus forming the ordinary acne-pimple, which ultimately suppurates, and discharges a minute quantity of pus; the spot then heals, leaving a small scar. In all severe cases of acne we find, in addition to the ordinary acne-spots, large pimples, resembling 'blind boils,' which suppurate slowly, and often leave very ugly scars. Acne develops in successive crops, so that as one set of pimples dies out, others appear, and thus the disease becomes chronic. Acne is almost always distributed symmetrically, so that both sides of the face and back are pretty equally affected. The exceptions to this rule are very rare.

DIAGNOSIS.—The differential diagnosis of acne is usually easy when the symmetrical distribution of the eruption and its period of development are taken into consideration. The two eruptions with which it is most likely to be confounded are: (1) certain forms of acne rosacea (*gutta rosea*), and (2) acne-like dermatosyphilis. Acne may best be distinguished from acne rosacea by the fact that this latter disease is chiefly met with in middle life, and is always attended with more or less general congestion of the face, and the subjective sensations of burning or tingling—characters which are absent in common acne. Acne rosacea is exclusively confined to the face, while common acne attacks also the shoulders and back.

Acne-like syphilitic eruptions are best distinguished by the absence of comedones; and by the tendency the pimples have to form into groups, which are not always symmetrical, and not strictly confined to the acne-regions. Some other syphilitic symptoms would probably be also present.

VARIETIES.—There is an interesting and somewhat rare eruption, commonly called *acne varioliformis*, which requires a very brief notice. In general appearance the pimples resemble those of acne, but are not especially associated with comedones. The eruption is usually confined to the scalp and upper part of the forehead, but is occasionally seen on the neck and chest. The scars formed by this disease are much deeper than those of common acne, and very closely resemble the pits left by small-pox. The region affected and the character of the scars are a sufficient guide to diagnosis. Recurrence is the rule.

TREATMENT.—As acne arises, for the most part, from the formation of comedones and plugging of the follicles, the treatment should be directed to stimulating the sebaceous glands of the skin to action, and hindering the growth of bacteria. For this purpose the application of sulphur is most useful. The sulphur may be applied in the form of an ointment or lotion. The objection to a lotion is, that during the night the powdered sulphur is apt to get into and inflame the eyes a little. There is not, however, the same objection to the use of a sulphur lotion during the daytime. A good plan is to apply a mild sulphur ointment or Wilson's hypochlorite of sulphur ointment every night, and wash it off in the morning with hot water, soap, and a soft flesh-brush. The daily use of a soft flesh-brush with hot water and soap is especially beneficial, as it prevents the formation of comedones.

When sulphur does not produce the desired effect, the linimentum saponis should be applied every night and allowed to dry on, and be washed off in the morning with warm water. In very severe

cases of acne, there are always a certain number of boil-like spots, which suppurate very slowly, and sometimes last for months without coming to a head. These boils should be carefully touched with a small piece of wood dipped in pure carbolic acid, or a saturated solution of potassa fusa in water; or the acid nitrate of mercury solution may be used, great care being taken that only the top of the boil is touched with the caustic. Cod-liver oil is the most generally useful tonic in cases of acne, but other tonics, as iron, are occasionally beneficial. For the treatment of acne varioliformis cod-liver oil, iodide of potassium, and arsenic are the best measures internally, while a dilute nitrate of mercury ointment may be used locally.

ROBERT LIVEING.

ACNE ROSACEA.—**SYNON.**: *Rosacea*; *Gutta rosea*; *Fr. Couperose*; *Ger. Das kupfrige Gesicht*.

DEFINITION.—A chronic inflammation of the face, attended with sensations of burning or stinging, and leading to a permanent enlargement of vessels and the formation of pimples.

SYMPTOMS.—There are two chief varieties of acne rosacea. The more severe form is met with chiefly in men, and is often the result of over-indulgence in alcohol. It especially attacks the nose, and leads to considerable enlargement of the vessels, and also, if of long standing, to hypertrophy of other parts of the skin, especially the sebaceous glands. The milder form of *gutta rosea* is very common in women after the age of thirty. In the first instance it may consist of a simple flushing of the face—generally of reflex origin, coming on at certain periods of the day, as, for example, after meals or in the evening. This congestion has, however, a tendency to become more persistent; and then, the vessels being permanently dilated, the redness does not entirely disappear, although it varies in degree from time to time. *Gutta rosea* in women is not confined to the neighbourhood of the nose, but usually extends in a butterfly-shaped patch to both cheeks, and sometimes to the forehead and chin. It is always attended with subjective sensations, which are generally those of burning, and less frequently of stinging or itching. Acne-like pimples are only occasionally met with, and when present are due to follicular inflammation. There is often seborrhœa nasi.

ÆTIOLOGY.—*Gutta rosea* in women is for the most part associated with cold hands and feet, and not uncommonly with dyspepsia and constipation, or irregularity in menstruation. In men, as before stated, the hypertrophic variety is sometimes, but by no means always, caused by over-indulgence in alcohol.

TREATMENT.—The severer form of *gutta rosea*, in men, is best dealt with by: (1) abstinence from alcohol; (2) the longitudinal division of the enlarged veins with a lancet, or the employment of electrolysis; and (3) the subsequent daily use of sulphur ointment, which should be well rubbed on every night. Great hypertrophy of the nose (*rhinophyma*) can only be removed by surgical methods. In treating *gutta rosea*, as it is commonly met with in women, the following points require special attention: (1) The diet should be most carefully regulated, and medicines ordered to remove, as far as possible, any dyspepsia or gouty tendency or any menstrual irregularity that may exist, and also to regulate the bowels. (2) A very mild sulphur (or hypochlorite

of sulphur) ointment should be applied in a small quantity every night, and washed off in the morning with warm soft oatmeal-water. In the daytime, a calamine and oxide of zinc lotion should be applied, and a little allowed to dry on. Gutta rosea is difficult to cure, but a steady perseverance in a rational plan of treatment will always produce a marked improvement in the disease, and sometimes quite remove it.

ROBERT LIVEING.

ACONITE, Poisoning by.—SYNON. : Fr. *Empoisonnement par l'Aconite*; Ger. *Eisenhutvergiftung*.—The common garden-plant, *Aconitum napellus*, known also as 'wolfsbane' or 'blue-rocket,' as well as other species of aconitum, are poisonous, and owe their poisonous properties to the presence of an alkaloid, *aconitine* or *aconitia*, or rather to a mixture of alkaloids passing under this name. The same or similar alkaloids have been obtained from the Indian aconite, *A. ferox*, and from Japanese aconite roots. All parts of *A. napellus* are poisonous. Aconitine is perhaps the most poisonous alkaloid known. All parts of the aconite plant when chewed, and aconitine when placed upon the lips or tongue, produce, after a few minutes, a disagreeable acrid burning sensation, followed by numbness, loss of sensibility of the part, salivation, and an after-sensation of searedness. These sensations may last for several hours.

The fresh root of aconite has frequently been eaten in mistake for horse-radish, to which it bears a remote resemblance. The root of horse-radish is whitish on the exterior, is long and of fairly uniform diameter, has a pungent odour when scraped, and the scraped surface retains its white appearance; whereas aconite-root is brown and conical, is destitute of pungent odour, and speedily acquires a pink colour when scraped and exposed to the air. Mistakes more frequently occur from liniments containing aconite being swallowed in error. In two cases the root has been administered with homicidal intent; and in one case a young man was killed by the administration of, as it is supposed, two grains of English aconitine. Accidents have also arisen from the administration of the potent English aconitine in mistake for the impure inert exotic or German alkaloid, or mixture of alkaloids passing under that name.

ANATOMICAL CHARACTERS.—After poisoning by aconite there may be gastric congestion or inflammation; but these may be absent.

SYMPTOMS.—When aconite, or any of its preparations, is taken by the mouth, the first sensation, transitory and mainly due to the action of the solvent, is followed in about three minutes by an intolerable burning and numbing pain, extending from the place of application to all the surrounding parts of the mucous membrane. There is salivation; and the burning sensation extends down the gullet to the stomach. Occasionally, when the poison has been rapidly swallowed, no marked symptoms may supervene for half an hour. The general symptoms are very varied, but may all be referred to weakening of the heart's action, disturbances of respiration, and paralysis of sensation on the surface of the body. This last may be described as 'numbness' or 'drawing of the skin,' or by some equivalent term. There is pain in the epigastrium, violent vomiting, and often purging; the pulse, at first rapid, quickly diminishes in frequency and force till it is imperceptible; the skin is cold,

clammy, and livid; respiration is laboured. The pupils, at first contracted, afterwards dilate; and this dilatation sometimes occurs suddenly and transitorily, and is accompanied by blindness. Convulsions are not common; but vomiting is often due to spasmodic contraction of the diaphragm, causing frothing at the mouth. Consciousness is retained till near the end of life.

DIAGNOSIS.—The peculiar sensation in the mouth—burning, feeling of searedness, numbness, &c., the great cardiac depression, and the difficulty of respiration, will generally serve to determine the nature of the case.

PROGNOSIS.—Death usually occurs within four or five hours. If the patient survive twelve hours, recovery is usually rapid and complete.

Fatal dose.—Of the root, sixty grains—probably much less might suffice. Of the pharmacopœial *tinctura aconiti* (1 in 20) half a fluid ounce to one fluid ounce. *Fleming's tincture* is about fifteen times as strong as the official tincture, and twenty-five minims have proved fatal. Four grains of the formerly official *alcoholic extract* have proved a fatal dose. English *aconitine* or *aconitia* (the alkaloid) is terribly potent: 1-2000th grain will produce a very decided sensation on the tongue, and it is probably as poisonous as the crystallised aconitine-nitrate, one-sixteenth of a grain of which has killed an adult within five hours.

TREATMENT.—In proceeding to treat a case of poisoning by aconite we must, first, wash out the stomach by means of the stomach-tube, and promote vomiting by warm emetics, of which carbonate of ammonium is the best. Stimulants must be freely administered by mouth or rectum; also strong black coffee or tea. Brandy and ether may be injected subcutaneously. Digitalis is a counter-poison, and may be administered with effect subcutaneously, in doses of twenty minims of the tincture, repeated in an hour or so if necessary. Inhalations of nitrite of amyl may afford some relief. The patient must be kept strictly in the recumbent position, warmth being applied to the surface; and, as a last resort, artificial respiration must be used. See POISONS.

THOMAS STEVENSON.

ACQUI, in the Province of Alessandria, Italy.—Thermal sulphur waters. See MINERAL WATERS.

ACQUIRED DISEASES.—Diseases which originate independently of hereditary transmission.

ACROCHORDON (ἄκρον, a point or end; and χορδή, a string).—An outgrowth from the skin, having the form of a slender cylinder. Such outgrowths are occasionally met with in elderly persons, especially on the neck or trunk. Microscopically, an acrochordon is composed of loose areolar tissue.

TREATMENT.—This consists in snipping off the outgrowths with scissors, in touching them with a strong solution of potassa fusa, or in applying the liquor plumbi fortis, or a 4 per 1000 solution of mercuric chloride.

JOHN HAROLD.

ACRODYNIA (ἄκρος, extreme; and δόλην, pain).—Acrodynia is the name applied to a disease epidemic in Paris in 1828. It was described by Alibert as a dermatitis, affecting particularly the palms and soles, accompanied by formication, anæsthesia or hyperæsthesia with stinging and smarting

pains. The pain may extend over the whole body, and be accompanied by gastro-intestinal disorder. The skin is at first bright red, then deeper tinted and brown, with subsequent pigmentation and desquamation, the cuticle sometimes being shed in a single piece. Occasionally there are pimples, pustules, and blisters. The disease runs a course of several weeks.

TREATMENT.—This consists in the treatment of the local inflammation by appropriate measures. See PELLAGRA; ERGOTISM.

JOHN HAROLD.

ACROMEGALY (ἄκρον, an extremity; and μέγας, large).—SYNON.: Fr. *Acromégalie*.

DEFINITION.—A remarkable dyscrasia, the striking characteristic of which is an enlargement of the bones, and most obviously of the bones of the hands and feet. Hence the name applied to it by Marie, who first described the disease in 1886, though other cases had been noted previously under different titles.

PATHOLOGY.—Acromegaly occurs most frequently, but not exclusively, in females between the ages of thirty and forty, but has been observed as early as fifteen and as late as forty-eight. It is very chronic; and though probably often fatal, it sometimes appears to become arrested after advancing for some years. In females it is usually preceded by early stoppage of the menses. Its relation to rheumatism is very doubtful.

Acromegaly is generally associated with enlargement or atrophy of the thyroid body; and enlargement of the thymus gland has been observed. In many post-mortem examinations tumours of the pituitary body have been met with.

DESCRIPTION.—In this disease the bones of the hands and feet are very greatly enlarged, but the long bones do not escape, the natural prominences and elevations being exaggerated sometimes to the dimensions of exostoses. The scapulæ, clavicles, and the sternal ends of the ribs become quite massive; the lower jaw also assumes vast proportions, the lower teeth spreading out and projecting far in front of those of the upper jaw. This gives a characteristic shape to the face, which is that of an egg with the large end downwards, as opposed to the oval of myxœdema, and the inverted egg-shape of osteitis deformans, with both of which diseases acromegaly may be confounded. The upper jaw and the cranial bones occasionally participate in the change. The bones, though enlarged, do not become curved; but the spine is often bent, so that the patient loses considerably in stature.

The cartilages of the nose, ears, eyelids, and larynx may be thickened; the last change probably accounting for an occasional great alteration in the voice.

The subcutaneous tissues are not obviously altered. The skin may be unchanged, but on the face it is apt to become coarse, and to show clearly the orifices of the sweat-glands. The hair does not become thin, as in myxœdema. Profuse perspiration and thirst are generally present.

The tongue is enlarged, and taste may be much impaired. Blindness is not uncommon, from atrophy of the optic nerve, possibly connected with a pituitary tumour. The sense of smell is often impaired; that of hearing does not appear to be modified, nor does that of touch.

There may be shortness of breathing, depending

upon asthmatic attacks, and the heart may be hypertrophied. The urine is not usually abnormal. The temperature is not raised. The intellect remains perfect. See MYXŒDEMA.

DIAGNOSIS.—It is not necessary to indicate the difference between this disease and osteitis deformans or myxœdema, the two diseases with which it is most likely to be confused, because, though there is certainly a superficial resemblance to each, the points of divergence are wide.

A somewhat similar disease, hypertrophic pulmonary osteo-arthritis, has lately claimed much attention. It was also first described by Marie. It occurs in persons suffering from chronic disease of the lungs. The face is unaltered, the deformity in the hands and feet is almost limited to the phalanges, and the spinal curvature is more marked than in acromegaly and confined to the lower dorsal and lumbar regions.

TREATMENT.—None of the numerous methods of treatment hitherto applied in acromegaly have proved of the slightest use. See BONE, Diseases of; OSTEITIS DEFORMANS.

RICKMAN J. GODLEE.

ACTINOMYCOSIS (ἀκτίς, a ray; and μύκης, a fungus).—DEFINITION.—A chronic disease, due to infection by a fungus known as *Actinomyces bovis*, attended by the formation of abscesses, chronic interstitial inflammation, or tumour-like growths of granulation-tissue, affecting various organs and structures of the body.

HISTORY.—This disease, which especially affects horned cattle and swine, and other animals which feed on grain, has long been known in them under various names, such as 'woody-tongue' in cattle. Its parasitic nature was demonstrated by Bollinger in 1876, and the name 'actinomycoses' or 'ray-fungus,' given by him, has since been employed to name the disease. Our present knowledge of the disease in man is due mainly to the researches of J. Israël (1877), Ponfick (1879), and A. Poncet and L. Bérard (1898). The work of the two latter writers is of especial value, and may be referred to for most of the literature.

ETIOLOGY.—The fungus which causes the disease may first be briefly described. The *Actinomyces* or *Oospora bovis* belongs to the Streptothricæ, an order of fungi intermediate between the higher bacteria and the mould-fungi. The spores (or conidia) grow into cylindrical threads which branch dichotomously, and form a radiating mycelium in which the threads are often densely felted together. The hyphæ are often much twisted, almost resembling spiral bacteria. As growth advances they frequently break into short segments, or rows of coccus-like bodies. These are not, however, regarded as true spores. The spores are formed in rows on special fruit-bearing hyphæ, which on a free surface grow up into the air. The spores are rounded, of somewhat larger diameter than the hyphæ.

The various shapes of the different elements of the growth, the presence in a colony of densely felted threads, irregularly twisted, of shorter rod-like bodies, and of ovoid and spherical spore-like bodies, has led to needless emphasis as to the 'polymorphism' of the fungus. All are simply stages of normal growth.

The tendency to radiating growth, whether in the tissues or in cultures, leads to the formation of spherical masses. These are well seen in a 'shake

culture' in gelatine medium, or in liquids. The central part usually undergoes degeneration, and has a hyaline appearance under the microscope, while in a liquefied culture it looks hollow. The dense felting of the filaments binds the mass together, and makes separation difficult, while it accounts for the presence of the little balls of the fungus in the puriform fluid from actinomycotic abscesses.

The character which especially attracts attention is the peculiar pear- or club-shaped swelling of the ends of some filaments. This is especially seen in the growth in the tissues, most markedly in bovine animals, the swollen ends often becoming calcified. But this character is not always well developed, especially in human actinomycosis, and the diagnosis must sometimes be made in its absence or with very partial development. In artificial growth it occurs only in old cultures, and is undoubtedly due to degeneration, with swelling of the sheath of the mycelium.

Cultivation of the fungus when once made can be easily continued, growth readily occurring in a great variety of media. But culture cannot usually be employed for diagnosis, as it is difficult to separate the other associated bacteria. Success is attained only by anaerobic culture at first, though aerobic growth is afterwards easy.

On agar-medium the colonies are usually hemispherical, discrete, of yellow beeswax colour, becoming very hard and cracked in the centre when about the size of a mustard seed. Sometimes they are whiter and small, the varieties depending largely on the moisture of the medium. On potato-paste the growth is especially characteristic, with the spore-bearing hyphae, and the surface powdered by the spores, and showing oily droplets. In gelatine-medium slow liquefaction takes place, and the colonies float as fluffy spheroidal balls with long filamentous offshoots in the liquid.

The spores have great vitality: when dry, they may be kept alive for three or four years. They are destroyed by exposure to moist heat of 75° C. for five minutes, while the mycelium is killed by shorter exposure to 60° C.

MODE OF INFECTION.—All the evidence at present attainable points to the extreme rarity of inoculation from diseased animals or from their flesh, although experimental inoculation has been successful. Some cases of alleged infection from cattle must be regarded as doubtful, for the disease is of very slow course, and other sources can hardly be excluded.

It is certain that the fungus is common on various cereals, although it is not certainly known what kind of grain most frequently harbours it. Some kinds of barley, including wild barley, appear especially liable. In a large number of recorded cases, a fragment of some cereal has been found embedded in the centre of the original focus of the disease, and in others the disease was known to have followed the lodgment of ears of barley or other corn. Indeed, although the fungus is probably common, and the spores have so great vitality and can be easily inhaled, some additional factor appears necessary in most cases to enable them to gain a hold on the tissues, and this may be afforded by such means as the presence of a large number of spores on the sharp awns of barley, which can penetrate and irritate the tissues. Chewing raw grain or straw, and inhaling dust in threshing, win-

nowing, or chaff-cutting are known modes of infection.

LESIONS OF ACTINOMYCOSIS.—The lesions of actinomycosis, like those of tuberculosis, present very great varieties in form, according to the organ affected, the intensity, duration, and character of the change produced, and the superadded action of other bacteria.

Most of the changes fall into one of two groups:—(1) a slowly progressive infiltration of 'granulomatous' type, resembling the chronic infiltrations of syphilis or tuberculosis; (2) a diffuse necrotic and suppurative change, leading to diffuse puriform infiltration or abscess-formation. The necrotic and suppurative changes seem especially apt to occur when the disease involves the viscera, and many bacteriologists believe them to be due to the added effects of septic bacteria.

In the suppurative forms the process may be somewhat acute, but more commonly it is at first slow, and has become advanced before any rapid necrosis or suppuration occurs. Around the colonies of fungus there is developed granulation-tissue modified in its arrangement by the nature of the virus. Each minute colony becomes surrounded by cells, some of which assume the epithelioid type; around these are zones of smaller proliferating cells and sometimes leucocytes, as with other parasitic irritants. Giant-cells are sometimes seen, but have not the peculiar characters or distribution found in tuberculosis. Indeed the only special character of the masses is the presence of the colonies of fungus, which are treated by the animal economy as all other irritating and noxious substances are, viz., by attempts to remove or destroy them, or to enclose them in a dense fibrous capsule. Hence from these younger cellular growths are formed masses of dense fibrous tissue, and the colonies of fungus may be arrested in growth and degenerate. It is especially in these denser fibrous masses that we find the older colonies, composed largely of radiating clubs, partly calcified, which were formerly regarded as the usual and typical form. Such are well seen in the 'woody-tongue' of cattle (see fig. 1). But if the growth is more rapid and cicatrization less complete, the colonies may be much larger and show little sign of clubs, except in some of the radiating offshoots. The various forms of mycelium, &c., already described, may then be seen.

Staining is easy and various methods may be used, such as carbol-thionin blue, methylene blue, or gentian violet. The colour is not discharged by iodine with Gram's method. The degenerated ends or clubs lose their affinity for aniline dyes, but are well stained with picricarmin or eosin.

In some of the cells which surround the colony, portions of the fungus are often seen. These cells, though probably phagocytic, may also serve to transport the fungus to other parts, and thus spread the infection. Although the extension is usually by slow continuous infiltration, widespread diffusion frequently occurs; this takes place especially, it is believed, by way of the blood-vessels. Indeed, one marked difference from tuberculosis is the comparatively slight involvement of the lymphatics and lymph-glands.

By this continuous infiltration, especially along the connective-tissue planes, large masses of granulation and fibrous tissue may be formed, resembling tumour-growths. But at some period local softening may occur, either purely necrotic or with actual

suppuration; and sinuses are formed which open on some free surface. As already stated, in some organs, a diffuse infiltration with softening and pus-formation is common. This is no doubt often aided by bacteria, especially by the common agents of suppuration; but a purely necrotic softening may also occur.

The 'pus' from the 'abscesses' is often thick, sometimes of peculiar odour, and contains minute particles, some of which may be visible to the naked eye, or with a lens, of sulphur-yellow colour, or sometimes greenish or black, especially where decomposition has occurred, as in the abdominal viscera. The detection and examination of these little masses, the

FIG. 1.—The woodcut shows the characters of a minute centre of growth in an actinomycosis-nodule from the tongue of a cow. The upper portion is sufficiently described in the text. The mass of fungus is represented as much less dense than in reality, otherwise no detail could be shown. (Magnified about 800 diameters.)

The lower four small figures show the characters seen in the same growth under a somewhat higher power. (1) A group of cells containing a cluster of the clubbed filaments. (2) A single cell with actinomyces growing in it. (3) A group of clubbed hyphae much larger than the others. (4) Filaments from centre of mass, showing bacillus-like characters, and branching of mycelium.

colonies of the fungus, are of especial diagnostic importance. They are somewhat hard and difficult to tease out, owing to the dense interlacing of the mycelium. In any suspected case, if they are not readily found, it is well to treat some pus with caustic alkali, mix with a quantity of distilled water, allow to settle in a conical glass, or separate with a centrifuge and then search carefully. If crushed, and stained with aniline dyes, they show the characteristic appearances, contrast-staining with picrocarmine or picric acid bringing out the 'clubs' well.

The general effects produced by these slowly spreading proliferative and necrotic changes vary much with the organ or tissue involved.

When upon a mucous membrane, slowly spreading ulceration and induration may occur, and the surface be covered by masses of epithelium containing the fungus. But after infection of subjacent parts has occurred, the ulcer may heal and the site of inoculation be thus obscured.

The infiltration may simulate a tumour, especially sarcoma, and cases of 'osteosarcoma' of the jaws &c. in cattle have proved to be actinomycotic. It may also resemble any of the so-called chronic inflammatory infiltrations, such as those of tuberculosis or syphilis. Finally it may cause chronic abscesses, usually following slow induration, but, in some organs, e.g. the liver, widespread necrotic and suppurative changes may occur.

SITES AND ORGANS INVOLVED.—Actinomycosis is one of the diseases which may affect almost any organ in the body or any group of organs, and which when once established may spread to distant parts. Cases are recorded of abscesses in the brain, kidney, ovary, thyroid gland, &c. But it especially occurs in regions adjoining the sites of easy lodgment of grain or like substances, which can convey the fungus. More than one half of the cases are in the cervical and maxillary regions, infection being by the gums, crypts of tonsils, pharynx, or more commonly by the buccal mucous membrane (Poncet). Next in frequency come the alimentary canal and peritoneum, the œsophagus and the cæcum being especially common starting-points. Then the lungs and pleuræ, and the mediastinum and the vertebæ. In the case of the lungs infection may enter through the bronchi, but in some cases has spread from the pharynx or œsophagus. Of other sites may be mentioned the skin, where the inoculation may be local, and the bones and periosteum, which are usually infected secondarily to some other tissue.

A brief account of some of the chief clinical forms must suffice.

The *tongue* is probably a not uncommon site in man as in cattle. Small nodules, resembling and probably often mistaken for syphilitic gummata, may be formed, and may cause ulceration or become indurated as in cattle. Probably many heal without secondary infection. Any part of the mouth, the gums, or buccal mucous membrane may also be primarily affected.

The *palpebral* and *conjunctival mucous membrane* may be locally affected; and the skin also of any part, especially that of the face and hands. But in most cases the affection of the skin and subcutaneous tissue is secondary to the formation of sinuses. It is probable that some intractable sores, analogous to Madura Foot, may be due to Actinomyces, although Madura Foot itself is now thought to be due to an allied species of fungus.

Where deeper infection and spread occurs, the locality will depend on the point of lodgment. If the infection is from the *buccal mucous membrane*, gums, or fauces, the 'cervico-maxillary' region is involved; if from the *pharynx* or *œsophagus*, that tube itself may be affected, with extension to the mediastinum, the vertebæ, and to the pleuræ and lungs, which may also be infected through the bronchi; if from the *stomach* or *intestines*, abdominal lesions, especially of the peritoneum, the liver, and more rarely of the kidneys and ovaries, are likely to occur.

But when once any extensive hold has been gained, infection may be carried to distant organs, such as the brain, by the blood-stream.

Cervico-maxillary forms.—In nearly two-thirds of the cases recorded the site of the principal lesions has been in the face and neck. According to Poncet the parasite usually enters by way of the buccal mucous membrane, and spreads to the tissues surrounding the temporo-maxillary articulation, or to the submaxillary region. The disease may extend up or down in various directions. Its course is usually subacute or chronic: sinuses are generally formed, sooner or later. If the periosteum is extensively involved, necrosis of bone may follow.

In this region actinomycotic lesions may simulate a variety of diseases, such as tumours of the jaw, chronic periostitis, tubercular enlargements of glands, and parotid tumours. They may, moreover, be complicated by secondary lesions in the brain, thorax, and elsewhere. Among the features of especial importance in the diagnosis from these various diseases are, according to Poncet, (1) the early and marked pain, (2) early trismus—due to the irritation of the masseter and temporal muscles—and especially common when the disease is in the temporo-maxillary region; (3) the peculiar swelling, which has an unequal and peculiar consistence; and (4) the relatively slight glandular enlargement. But in many cases the diagnosis is uncertain until sinuses appear, or until careful exploration has shown the presence of the fungus.

Abdominal forms.—In the abdominal forms infection appears to start most commonly from the large intestine, especially the cæcum, including the ileo-cæcal valve and vermiform appendix. In some cases the source of infection has been traced to foreign bodies embedded in the mucous membrane. Various forms of intestinal ulceration are occasionally found. There is an especial tendency to adhesions and thickening of the peritoneum, with the formation of chronic abscesses, which burrow in various directions, and sometimes involve adjacent organs. These chronic peritoneal lesions give rise to most of the symptoms and physical signs met with in this form of the disease.

Liver.—Actinomycotic abscess of the liver has been frequently observed. It is practically always secondary to infection from the intestine or some other part. It may, however, be the most obvious lesion during life. The abscess may be solitary, with adhesions and induration around; or it may be multiple, especially where infection is through the portal vein, and other organisms accompany the actinomycetes; or there may be a diffuse infiltration, with widespread necrosis. Enlargement of the organ may usually be detected, and may be great, but if the abscess is deeply seated in the upper or posterior part, it may, as in tropical abscess of the liver, be difficult to diagnose. It may simulate cancer, solitary or multiple, or other hepatic enlargement. Except in the more rapid forms, where the fever may be like that either of chronic or of acute tropical abscess of the liver, the disease gives rise to no special hepatic symptoms.

Thoracic and pulmonary forms.—Ulceration or stricture of the œsophagus may occur. The disease may spread in the mediastinum and may involve the vertebræ and ribs. It may extend to the pleuræ and thence to the lungs, or inversely from the bronchi to the lungs and pleuræ. In the *lungs and pleuræ* the symptoms are those of very chronic phthisis or of interstitial pneumonia, with pleural thickening, followed by some gradual excavation. The formation of sinuses through the

chest-wall is not uncommon, the periosteum and bone of the ribs being often infiltrated and destroyed in the course of the disease.

In the majority of cases of pulmonary lesions the bases are involved while the apices remain free. Pyrexia may be slight or absent; the temperature is much less irregular than in tuberculosis, and does not show marked evening rise. The sputa are often fetid at an early period, before marked signs of cavity-formation appear; while hæmoptysis and nummular sputa are rare. There is less disturbance of respiration, and far less impairment of general health. The lymphatic glands in the neck and axillæ are not enlarged (Poncet and Bérard). There may be serous pleuritic effusion. Upon the whole the pulmonary forms more resemble obscure interstitial pneumonias or new-growths in the lung than phthisis—at least during a considerable part of their course. The detection of the fungus in the sputa may be the only means of positive diagnosis, and in some cases it has not been found, though carefully and repeatedly sought for.

TREATMENT.—Treatment is mainly of two kinds, medicinal and operative. But it must be especially insisted on, that actinomycosis is a disease against which there are strong natural powers of resistance, and that the parasite gains hold with difficulty in most healthy subjects, and may be overcome even when it has gained a lodgment. Hence the great importance of all means of increasing the general health, and of avoiding any source of irritation, or of septic infection.

Medicinal Treatment.—Potassium iodide in large and increasing doses has proved successful in many cases in aiding the arrest of the disease, although it is not in any sense a specific. In early cases it should always be employed in addition to surgical means, or where these are not available. When the disease is only diagnosed late, or if bacterial infection has occurred, it may entirely fail, though its use even here has not proved injurious. It does not act directly on the fungus, for one per cent. of potassium iodide in culture-media does not prevent the growth of the parasite. The doses may begin with thirty grains daily, and rise to ninety grains or more. Other iodides have not yet been sufficiently tried.

Operative Treatment.—In cases in which the disease is accessible, operation is usually beneficial, even if the entire extent of the infiltration cannot be reached.

Free excision, with curetting or scraping, should be employed, followed by irrigation with antiseptics; the exact steps varying with the site and extent of the disease. Of the antiseptics corrosive sublimate has been most used, but it is almost certain that a solution (in excess of potassium iodide) of biniodide of mercury (1 in 4,000), with addition of 10 per cent. of glycerin, would be far more effective, from its greater antiseptic and penetrating power. Iodide of starch paste, to which the solution of biniodide of mercury in the proportion of 1 in 8,000 has been added, is valuable as a continuous application. Where possible, the eradication of all infected tissues is desirable, but where less complete removal is possible, much benefit may follow partial removal, if free access is left for antiseptic applications and for spontaneous evacuation. This applies even to lesions of internal organs.

The injection of antiseptic solutions into the nodules, which has been advocated, is not without

risk, and should never be employed where excision is possible, or where any serious risk would be incurred by acute inflammatory reaction and swelling, which usually follow. In any case, the closure of the wound should not be premature, as it is rarely possible to be sure that all the foci of the disease have been reached.

Of other suggested lines of treatment, such as by antagonistic sera, or by mixed culture-fluids, by tuberculin, and so on, it may be stated that no protective or antiserum has yet been produced, nor has any benefit resulted from the substances tried hitherto. Such treatment is of course possible in the future, but in advanced cases the use of the knife will probably still be essential.

PROPHYLAXIS.—What has been stated on the mode of infection sufficiently indicates the measures needed. Ordinary cooking would destroy the infection of meat, which can hardly ever be the actual source. Except for those who have to attend diseased cattle, the recognition of the possible modes of infection by grain, and means to avoid risk, are chiefly necessary.

Further knowledge of the exact kind of grain most affected, and of any ready means of the detection and prevention of its invasion by the parasite, would be of great value. W. S. GREENFIELD.

ACUPUNCTURE (*acus*, a needle ; and *punctum*, a prick).—SYNON. : Fr. *Acupuncture* ; Ger. *Nadelstich*.

DESCRIPTION.—Acupuncture is an ancient mode of treatment for the relief of painful affections, now but little used, consisting in the introduction of fine round needles through the skin, to a varying depth. The needles used are about two inches in length, and are set in round handles, so that they can be introduced with a gentle rotatory movement. Acupuncture is now employed chiefly in lumbago and sciatica, in which affections it undoubtedly may give relief. The operation is thus performed:—the patient being laid upon his face, tender spots are sought for—in lumbago over the erector spinæ, in sciatica along the course of the sciatic nerve. The needles are then pushed in vertically for a depth of from one and a half to two inches, and allowed to remain for from half an hour to two hours. The number of needles employed may vary from one to six. In sciatica it is recommended, if possible, to make the needle actually penetrate the nerve. This result is known by the patient complaining of sudden pain shooting down the back of the leg. The mode of action is uncertain, but in sciatica it has been supposed that the puncture of the nerve-sheath allows the escape of fluid.

ACUTE.—This word, when associated with a disease, signifies that such disease runs a rapid course, and is attended with urgent symptoms. It is also employed to express intensity of a particular symptom, e.g. an acute pain.

ADDISON'S DISEASE.—SYNON. : Bronzed Skin Disease ; *Melasma Addisonii* ; Fr. *Mélano-dermie Asthénique* ; *Maladie d'Addison* ; Ger. *Addison'sche Krankheit*.

DEFINITION.—A constitutional disease characterised by extreme muscular weakness, asthenia, a tendency to syncope, nausea, vomiting, and an exaggeration of the normal pigmentation of the skin. After death alteration of the suprarenal bodies is the chief lesion found.

Although pigmentation is one of the most striking signs of the fully developed disease, there are cases without any pigmentation where the symptoms come on acutely, rapidly lead to death, and are found to be associated with extensive disease of the suprarenal capsules. This condition is spoken of as '*Addison's disease without pigmentation*,' and is possibly due to acute insufficiency of the suprarenal glands.

HISTORICAL.—This disease was first described in 1854 by Thomas Addison, physician to Guy's Hospital. The discoverer's name was subsequently attached to the disease by Trousseau.

FREQUENCY.—This is a rare disease and is probably diagnosed erroneously more often than it is overlooked. It appears to be less rare in this country than in America. Its detection in dark-skinned races is a matter of great difficulty.

It is commoner in males (65 per cent.) than in females (35 per cent.) and occurs most often about 30 years of age, though it has been met with at both extremes of life (one week and eighty-one years). There is no evidence that it is proportionately rarer in the well-to-do than in the labouring classes.

ÆTIOLOGY.—As 80 per cent. of the fatal cases are due to tubercular disease of the suprarenal capsules, it has been thought that the disease is more likely to occur in families where tuberculosis is rife. This is, however, rather an assumption than a proved fact. Exceptionally it has been known to kill two members of the same family ; probably in such instances the resistance of the suprarenal glands is particularly low. Blows on the back or strains from laborious occupations have been regarded as disposing to tubercular infection of the capsules. It is possible that traumatism by giving rise to hæmorrhage into the suprarenal bodies, such as is not uncommonly seen in still-born children after difficult labours, and occasionally in later life after severe injuries, may so reduce the resistance of the organs that tuberculosis develops there more readily.

In some instances the suprarenal bodies are the only parts of the body showing tuberculosis ; but usually other organs are affected, and in a certain proportion of fatal cases the disease is found to have spread by continuity from tubercular osteitis of the vertebrae.

MORBID ANATOMY.—In about 80 per cent. of the fatal cases the suprarenal capsules show tuberculous infiltration : this is undoubtedly their most frequent condition, but other lesions may give rise to Addison's disease.

The tubercular change begins in the medulla as granulation-tissue, which becomes in due course caseous, and may either dry up, become calcified, or soften down into a puriform fluid. The tubercular inflammation spreads to the cortex and from thence to the tissues around. In this way the important sympathetic plexuses and ganglia may become involved. The suprarenal bodies become enlarged, deformed, and nodular. Bacteriological examination leaves no doubt as to the tubercular nature of the change.

In some exceptional, but typical, cases of Addison's disease the suprarenal capsules show atrophy without any inflammatory change ; the atrophy may be so extreme that only a yellow streaking of the fat in the normal situation of the glands is left ; it is not surprising therefore that their absence is sometimes recorded. Chronic inflammation with atrophy, there being no evidence of tuberculosis, is the lesion

found in a small percentage of cases. Very occasionally some of the symptoms of Addison's disease are manifested when secondary malignant growths are present in the suprarenals; these cases are naturally not typical, since the patient is suffering from two morbid conditions—malignant disease of some other part of the body and suprarenal inadequacy. Primary malignant growth of the suprarenal bodies does not present the clinical features of typical Addison's disease. In a few fatal cases of the disease the suprarenal bodies themselves are healthy, while there is some lymphadenomatous or other growth in the immediate neighbourhood which may involve the adjacent sympathetic or compress the efferent lymphatics and veins of the gland.

The *sympathetic nerves and plexuses* in the immediate neighbourhood of the affected suprarenal bodies are frequently invaded by inflammatory tissue and microscopically degenerated; in other instances, as in simple atrophy of the suprarenal glands, they are healthy. The inconstancy in their condition is strong evidence against the view that the symptoms of Addison's disease depend solely and entirely on irritation and neuritis of the great sympathetic plexuses in the neighbourhood of the suprarenal glands.

Other morbid lesions.—The heart is small and atrophied. The lymphoid tissue in the alimentary canal is often increased in amount. The thymus has sometimes been found to be persistent and the spleen softened: these last lesions are by no means constant.

PATHOGENY.—The relation of the morbid changes in the suprarenal glands to the symptoms of Addison's disease has given rise to a great deal of discussion. Three theories may be mentioned. (1) The *nervous* theory—that the symptoms depend on the irritation of the sympathetic nerve-fibres either in the solar and other large plexuses, or of those actually embedded in the suprarenal glands, and are really independent of the functional destruction of the glands themselves. For the reason given above this view is no longer accepted as a complete and exclusive explanation. (2) *The theory of suprarenal inadequacy*—that the symptoms are due to an absence of the normal internal secretion of the glands: Addison's disease would thus be analogous to myxedema. This theory is supported by experiments on animals and by the fact that two prominent symptoms of the disease—low blood-pressure and loss of muscular tone—are the exact converse of the physiological effects of suprarenal extract. The absence of the normal internal secretion might theoretically lead solely to a condition of apathy and want of tone, or in addition, by upsetting the metabolism of the organism, to a toxæmic state. The theory of suprarenal inadequacy is widely accepted at the present time, but there are difficulties in accepting it, such as the facts that in some cases the glands are extensively destroyed without symptoms, that in other instances symptoms are present in association with healthy glands, and that the administration of suprarenal extract so frequently fails to relieve the symptoms. (3) *The theory of nervous irritation and glandular inadequacy*—that while some cases are due to glandular inadequacy alone, others are due to this factor plus irritation of the sympathetic plexuses in the immediate vicinity. Under treatment by suprarenal extract the cases of the first category improve while those in the second category receive little or no benefit.

CLINICAL COURSE AND SYMPTOMS.—The onset is usually very insidious and slow, but sometimes the patient dies of acute symptoms that have rapidly developed without any suspicion having arisen as to the existence of disease of the suprarenal bodies: the nature of the disease is then only revealed at the autopsy. In an ordinary case there is gradually increasing weakness and loss of muscular power accompanied by dyspepsia, loss of appetite, and gastric disturbance. The heart's action becomes depressed, the pulse is of low tension, remarkably soft and weak, and there is shortness of breath on exertion and a tendency to syncope. The loss of strength and vigour is out of all proportion to the general nutrition; anaemia is rarely a prominent feature. The temperature is, like other functions, depressed, fever and leucocytosis being exceptional, and when present probably due to some complication. Mental apathy and depression are marked features in most cases. Headache, giddiness, sighing, yawning, or hiccough may develop as the disease progresses. Pain in the back, thought to be due to traction on the nerve-fibres around the suprarenal bodies, may be troublesome, while pains in the joints and limbs are occasionally observed. Nausea, retching, vomiting, and flatulence may be very prominent and recur over long periods; sometimes vomiting may so exhaust the patient as to bring him to death's door. Epigastric pain and 'sinking' feelings are not uncommon. The urine does not present any constant or characteristic features.

After a varying interval pigmentation appears; in rare instances it is the first thing noticed, but usually it is preceded by constitutional symptoms and in acute cases may be absent. It is an exaggeration of that seen in health and is increased by any irritation, so that the exposed parts of the body and those liable to pressure by dress, &c., become pigmented; the face, neck, backs of hands, arms, anterior folds of axillæ, the shoulders, nipples, spine, waist, linea alba, genitals, and the knees are likely to be darkened; while the nails, palms, soles, and scalp where it is covered by hair, are not affected. The writer has, however, seen marked pigmentation of the palms. Around scars or blisters the pigmentation is exaggerated. The hair becomes darker. Small black spots like moles may also develop on the skin. Occasionally the disease is associated with leucoderma. The pigmentation may vary considerably in degree even within quite short periods of time. The patient often feels worse when the skin is darker, and *vice versa*. In some cases the pigmentation may be like that of the darker races, but it is noticeable that the nails are quite free from darkening. Often the bronzing is like that due to sunburn, while sometimes the skin merely looks dirty.

The pigment, melanin, is that normally present in the stratum Malpighii of the epidermis, only it is manufactured in larger quantities; the material from which it is formed is apparently conveyed to the stratum Malpighii from the blood-vessels of the corium by 'carrier cells.'

Pigmentation of the mucous membrane of the lips, the tongue, and inside of the mouth occurs much less frequently and appears to be due to some manifest irritation, such as carious teeth. The conjunctivæ are usually pale and contrast with the bronzed skin of the face, but in rare instances pigmentation has been noticed in them.

From time to time the patient has attacks in which all the symptoms are exaggerated; sometimes the pulse becomes extremely feeble and with difficulty felt at the wrist; vomiting or, rarely, diarrhoea may become uncontrollable and kill the patient. If the patient survive an attack he rallies, but is left permanently weaker. As time goes on the general condition deteriorates until a final exacerbation carries him off; sometimes death occurs suddenly, with little warning, from syncope.

Death may be preceded by convulsions, by delirium, by coma, or by a period of such extreme weakness that although quite conscious the patient can hardly make any sign of life.

DURATION AND PROGNOSIS.—The *duration* of the disease varies very widely: the extremes are ten years in the most prolonged cases and a few days in fulminating or acute cases. In chronic cases the disease may become latent, and it is possible that it may sometimes remain so: at any rate cases so diagnosed by most competent authorities have been known to live for very many years and die from other causes. In hospital cases the average duration is said to be about two years, while in persons better provided with the comforts and luxuries of life five or six years may elapse between the onset of symptoms and a fatal termination.

The *prognosis* is very bad; when the disease is sufficiently marked to be definitely diagnosed, a fatal termination must sooner or later be expected. The course of the disease is, however, very irregular, and intervals of fair health may sometimes occur even when the patient has been extremely weak. On the other hand, death may occur suddenly from syncope early in the course of the disease. Progressive loss of strength and shortness of breath with increasing apathy are bad symptoms. There is some reason to think that the outlook is better in those cases that improve under suprarenal extract.

DIAGNOSIS.—In well-marked cases there is little difficulty. The association of extreme debility with the characteristic pigmentation in the absence of any discoverable cause should always suggest the disease. In cases without pigmentation the diagnosis is difficult and is made by a process of exclusion; pernicious and other anæmias should be eliminated by examination of the blood; latent malignant disease of the stomach might be suggested by the ascertained absence of hydrochloric acid from the gastric contents. Pigmentation of the skin occurs in a number of conditions, but is not necessarily associated with debility and gastro-intestinal symptoms. In a woman pigmentation and vomiting may occur in pregnancy. In hæmochromatosis the pigmentation may imitate that of Addison's disease, but there is usually diabetes mellitus (*diabète bronzé*), and frequently enlargement and cirrhosis of the liver at the same time. In malarial cachexia melanæmia and melanoderma may occur, but the history, the enlarged spleen, and the examination of the blood should prevent mistake. In phthisis, chronic peritonitis, and granular kidney, the face may be considerably pigmented. In exophthalmic goitre, rheumatoid arthritis, syphilis, pellagra, and extensive melanotic sarcoma of the liver, the skin is occasionally markedly pigmented, but the other features of the primary disease can hardly be overlooked. In *acanthosis nigricans* the skin is warty and rough as well as pigmented and is thus distinguished from Addison's disease. See **ACANTHOSIS NIGRICANS**.

The dirty colour of the skin due to past jaundice

is hardly likely to be mistaken for the bronzing of Addison's disease. Long-continued irritation of the skin by pediculi, combined with abstinence from washing (vagabond's disease), imitates the pigmentation of Addison's disease, but yields to soap and water.

Men employed in gas- and tar-works, or those much exposed to heat and weather, naturally become bronzed, while a long course of silver (argyria) or arsenic may produce very noticeable pigmentation.

TREATMENT.—When the disease is diagnosed the patient should adopt a quiet life and retire from work that makes any demands on his physical or mental powers. He should live in the country in a sunny bracing place protected from cold and east wind and not subject to rapid alterations of temperature. When the general condition is good, gentle exercise may be allowed, but fatigue, worry, and strain must be carefully avoided. Any faintness should be the signal for complete rest in the horizontal position for some days.

The *Diet* should be simple and nutritious: meat should be given, and stimulants when required. When vomiting occurs the diet must be modified so as to minimise the irritation of the stomach and to keep up the patient's failing strength. Ice may be sucked before food; liquid and predigested food should be given cold in small quantities and at more frequent intervals; and iced champagne may be employed as a stimulant.

Medicinal treatment may be divided into (1) the administration of suprarenal gland-substance and (2) symptomatic treatment.

Suprarenal gland-substance is usually given in the form of an extract; but the glands of sheep have been given in a sandwich. Oliver and Schäfer have shown that the physiologically active extract, which is only obtained from the medulla of the suprarenal bodies, is not destroyed by contact with gastric juice *in vitro*, and hence the extract has been largely given by the mouth. Nevertheless it is not by any means certain that suprarenal extract taken by the mouth is so effective as hypodermic injection. When given by the mouth a quantity of the extract equal to 15 grains of the gland should be given twice a day at first, and gradually increased until an amount equal to two drachms of the gland substance is taken daily. If any stiffness of the muscles, sickness, or depression arise, the administration of the extract should be temporarily stopped, though ill effects can but very rarely be traced to the extract. Hypodermic injections should be tried, if administration by the mouth fails: the initial dose should be about one-third of that given by the mouth and should be increased cautiously. The effects of this form of treatment are disappointing as compared with those of thyroid-extract in myxœdema; temporary improvement, sometimes of a very striking nature, may occur, but relapses are not prevented by it.

Tonics such as iron, strychnine, and arsenic may be given, and, if it can be borne, an emulsion of cod-liver oil. Vomiting should be combated by salts of bismuth, oxalate of cerium, and small hypodermic injections [$\frac{1}{40}$ – $\frac{1}{20}$ gr.] of morphine. Diarrhoea should be controlled by opium and bismuth. If constipation occur, mild purgatives only must be employed, since vigorous treatment in this direction may be followed by severe symptoms. It does not appear that surgical treatment can be invoked with much likelihood of success. H. D. ROLLESTON.

ADENALGIA (ἀδὴν, a gland; and ἄλγος, pain). Pain in a gland.

ADENITIS.—Inflammation of a gland. See the several glands.

ADENOCELE (ἀδὴν, a gland; and κήλη, a tumour).—A tumour connected with a gland.

ADENODYNIA (ἀδὴν, a gland; and ὀδύνη, pain).—Pain in a gland.

ADENOID (ἀδὴν, a gland; and εἶδος, form).—Glandular: resembling the structure of a gland, whether secreting or lymphatic. The term 'adenoids' is often used to denote certain post-nasal growths. See NOSE, Diseases of.

ADENOMA (ἀδὴν, a gland, and the termination *oma*, adopted to indicate a tumour).—A morbid growth, the structure of which is of glandular nature. See TUMOURS.

ADENOMA SEBACEUM.—SYNON.: *Nævus sebaceus* (Bandler); *Excrescences vasculaires* (Kayer); *Nævus pilosus cornutus* (Darier).

DEFINITION.—Multiple tumours consisting of hypertrophied sebaceous glands, situated on the face, and of congenital origin, although not usually present or noticed at birth.

ÆTIOLOGY.—The disease is congenital, but is seldom noticed before the sixth or seventh year, and often not till puberty, when it usually becomes much aggravated. The growths, which are purely hypertrophic in character, arise from isolated portions of the germinal epithelium, thus justifying the contention of Bandler that they ought to be classified as forms of *nævus*, using the word in its broadest sense. In a very large proportion of cases the patients are mentally defective, many being epileptics, hystero-epileptics, or idiots. Such patients are usually relegated to asylums, and the existence of the disease, which is by no means extremely rare, often passes unrecognised. Other nævoid conditions of skin are usually co-existent, e.g. warts, moles, vascular, hairy, or pigmentary nævi, and fibromata, often in great abundance. In exceptional cases analogous hypertrophic changes, both as regards number and size, occur in the sweat-glands, constituting, according to Radcliffe Crocker, a 'pilo-sebaceous hidradenoma.'

SYMPTOMS.—The disease manifests itself as little nodules or tumours situated on the face and in those regions of it where the sebaceous glands exist in greatest abundance. Thus they are most numerous and most closely crowded together on the nose and naso-labial folds; less so on the cheeks and chin; and least of all on the forehead. The distribution is, therefore, much the same as that of rosacea, which sometimes complicates adenoma sebaceum, increasing the disfigurement materially. The essential nodules vary in size from a pin's point to a split pea; they are firm and painless, standing out boldly from the skin-surface. Although closely grouped together they never coalesce to form plaques. The epidermis over them is generally smooth, but exceptionally harsh and even warty. When the nodules are pricked and squeezed, inspissated sebum emerges. In uncomplicated cases the little tumours are waxy, yellowish or brownish in tint; but in almost all cases there is much vascular telangiectasis both over and around the sebaceous tumours, so that the affected area assumes

a pink or even vivid red colour. When these blood-vascular changes are abundant—and they may even mask the essential lesions—the disease is said to be of the 'telangiectatic type.'

PATHOLOGICAL ANATOMY.—The epidermis is usually normal, but its interpapillary prolongations may be hypertrophied. The increased thickness of the cutis is due to a great increase in size and complexity of the sebaceous glands, the cells of which are, however, of normal size, and functionally active. Around the growths there is no small-celled infiltration or other inflammatory or hyperplastic change.

PROGNOSIS.—Adenoma sebaceum usually attains its maximum of intensity at or about puberty, after which it remains unaltered as a rule. Occasionally spontaneous absorption or cystic degeneration in the centre of the nodules may occur, leaving depressed scars; but such occurrences are rare. The subjects of the disease are, naturally, almost always short-lived.

DIAGNOSIS.—The disease may be simulated by xanthoma, adenoma of sweat-glands, colloid milium, lymphangioma or even nodular lupus vulgaris. Excision and microscopical examination of a nodule will readily clear up all doubt.

Unilateral or asymmetrical patches of hypertrophied sebaceous glands may arise in adult life and in persons of normal intelligence, but the writer is of opinion that they ought to be carefully differentiated from adenoma sebaceum.

TREATMENT.—Discrete growths may sometimes be satisfactorily destroyed by electrolysis, the negative pole and a current of about five milliamperes being employed. More closely grouped lesions may be occasionally successfully treated by repeated scraping, curetting, and scarification; or more localised patches may be excised, Thiersch-grafts being afterwards applied. See SKIN-GRAFTING.

J. J. PRINGLE.

ADHESIONS.—Structures are said to be *adherent* when they become abnormally united together, the morbid formations by which this union is effected being termed *adhesions*. These are most frequently met with in connection with serous surfaces, being usually the result of an inflammatory process, but they may be observed in other structures. Adhesions vary considerably in extent, number, mode of arrangement, firmness, and other characters: they may merely consist of a few loose, slender, and delicate bands; or these bands may be thick and strong; or the contiguous surfaces may be blended and matted together to a greater or less extent, so that they cannot be separated without tearing or cutting them asunder. In structure adhesions consist of fibrous tissue.

EFFECTS.—Adhesions are often found at post-mortem examinations, which have been of little or no consequence during life, as, for instance, many of those which form in connection with the pleural surfaces. If, however, they are extensive and firm, or if they occupy certain regions of the body, they may prove of serious moment. The principal evils which are liable to result from adhesions may be thus indicated:—1. They often bind parts together, and interfere with the movements of important organs, such as the lungs, heart, stomach, or intestines; in this way preventing the due performance of their functions. 2. When an organ is displaced in any way, as, for example, the heart by

pleuritic effusion, it may become fixed in its new position by the formation of adhesions, its functions being thus disturbed. 3. It is highly probable that extensive adhesions may lead to hypertrophy of an organ, e.g. the heart, by embarrassing its movements, and hence affecting its action. 4. On the other hand, atrophy or degeneration of structure may ensue, in consequence of the adhesions interfering with the due supply of blood by pressing upon the vessels, so that the nutrition of the tissues becomes impaired. In the young, also, their development may be checked. 5. Adhesions may involve important structures, such as nerves or vessels, pressing upon or destroying them, thus giving rise to symptoms of a serious nature. 6. Tubes or canals for the passage of secretions or other materials are sometimes narrowed or obliterated by adhesions. 7. When formed within the abdominal cavity, especially when they take the form of bands, adhesions may prove highly dangerous by compressing, constricting, exerting traction upon, or strangulating some portion of the intestine, in either of these ways leading to intestinal obstruction.

It is frequently difficult or impossible to determine the existence of adhesions by clinical investigation during life; but the history of some past illness during which they were likely to be formed, the results of physical examination, especially in connection with the heart and lungs, and the symptoms present, not uncommonly enable them to be discovered. FREDERICK T. ROBERTS.

ADIPOCERE (*adeps*, fat; and *cera*, wax).—

SYNON.: Fr. *Adipocire*; Ger. *Fettwachs*.

DEFINITION.—A fatty substance formed in the process of decomposition of animal bodies in the presence of water.

DESCRIPTION.—In appearance adipocere is a waxy substance, varying in colour from white to darkish brown. When moist it is soft and greasy; when dry it 'somewhat resembles spermaceti in appearance, but is less crystalline in fracture' (Quain). Traces of the structure of the parts from which it has been formed may be present in the form of blood-vessels, muscular fibres, or connective tissue: to such is due the reticulum of insoluble matter left when adipocere is dissolved in ether. It has a peculiar unpleasant odour, which becomes stronger on heating. Its density is lower than that of water.

CHEMICAL COMPOSITION.—Adipocere is probably not a definite chemical compound, but a mixture of different substances, the proportions of which may vary according to the conditions of its formation. In this way the differences observed in its colour and consistency may be explained. Analysis by Chevreul showed it to consist of an ammoniacal soap, containing traces of colouring matter, of a bitter principle, and of a volatile odorous substance. The fatty acids present are palmitic, stearic, and oleic, the first of these being in great excess, while the oleic acid which forms so large a constituent of human fat is found in very small quantity (Wetherill). In many specimens which have been formed in water containing a large amount of calcium-salts, a quantity of lime-soap is found along with the ammoniacal compound. In such cases the lime is probably a substitution-product, replacing the ammonia in the previously formed adipocere (Orfila).

METHOD OF FORMATION.—In order that formation of adipocere (saponification) may take place, it is necessary that there should be present not only fatty acids, derived from the breaking up of animal fat, but also a supply of ammonia to act as a base. The latter is derived from the decomposition of the proteid portions of the body. The fatty acids are mainly derived from the normally existing adipose tissue, but parts which contain little fat may also be converted into adipocere. In this case the proteid-molecule probably breaks down and gives rise to a fatty substance, which is subsequently saponified. The presence of water in considerable quantity is necessary for the formation of adipocere, which therefore occurs in bodies which have been buried in damp soil or left lying in ponds or rivers. Warmth is favourable to the process, which takes place with great rapidity in tropical countries. The outer parts of the body suffer first, and the process spreads irregularly inwards. Portions containing much fat, such as the buttocks, breasts, and hollows of the cheeks, are rapidly saponified: the abdominal viscera are next affected, and the muscles still later. Fat persons and children are favourable subjects for this form of change, which is also facilitated by the existence of other decomposing matter in the neighbourhood, whereby a free supply of ammonia is provided. Thus bodies which have lain in a cesspool or in a crowded damp graveyard will be readily saponified. Since bacterial action is necessary for the decomposition of animal bodies, it is evident that it is a necessary factor in the production of adipocere.

MEDICO-LEGAL IMPORTANCE.—When once formed adipocere remains unaltered for an indefinite period of time. It thus tends to preserve the features of dead bodies from the effects of decomposition, and to render identification possible. It also perpetuates the exact nature of any wounds or injuries received, by causing the parts to maintain their shape and mutual relations. Its formation is further of some importance as an aid to estimating the length of time which has elapsed since death. Unfortunately no very definite limits of time can be laid down for the commencement and progress of saponification. In India instances have been observed in which large portions of dead bodies were converted into adipocere in two or three days (Mackenzie). In temperate climates it is probable that little saponification will be found in less than five or six weeks. An instance is, however, quoted by Taylor in which a body which had lain in running water was converted into adipocere in five weeks, so that the change in this case must have begun much earlier. It is necessary to take into consideration the conditions to which a body has been subjected in order to estimate the rapidity with which adipocere may be formed. In hot weather, in shallow water and in presence of decomposing animal matter, superficial parts might be saponified in temperate climates in two or three weeks, but total conversion of soft parts into adipocere would seldom occur under ordinary conditions in less than three or four months, probably because the conditions of moisture necessary for its formation are usually here associated with a degree of cold by which decomposition is materially retarded. In the majority of cases the process is considerably slower even than this, and years may elapse before saponification is complete.

WM. CECIL BOSANQUET.

ADIPOSIS.—A term which properly signifies either general corpulency, or accumulation of adipose tissue in or upon an organ. See **FATTY GROWTH**; and **OBESITY**.

ADIPOSIS DOLOROSA.—A disease of middle life, occurring principally in women, characterised by the formation of irregular masses of subcutaneous fat, and occasionally by degenerative changes in the nerves of the affected areas and in the thyroid gland. The symptoms are pain and tenderness, and in some cases impaired sensibility. The administration of thyroid extract is occasionally beneficial.

ADIRONDACK MOUNTAINS, In New York State.—A series of ranges rising from a plateau 2,000 feet above the sea, with picturesque lakes between them. Highest altitude, Marcy, 5,337 feet. Commodious hotels on the shores of the lakes. Much frequented as a summer climatic resort. Recommended in phthisis. See **CLIMATE**, Treatment of Disease by.

ADRENALS. See **SUPRARENAL GLANDS**.

ADYNAMIC (ἀ, priv.; and δύναμις, power).—A term indicating serious depression of the vital powers. The adjective is applied to diseases in which the so-called 'typhoid condition' is especially liable to occur. See **TYPHOID STATE**.

ÆGOPHONY (αἴξ, a goat; and φωνή, voice).—A peculiar alteration of the resonance of the voice, as heard on auscultation of the chest, compared to the bleating of a goat. See **PHYSICAL EXAMINATION**.

ÆTIOLOGY (αἰτία, cause; and λόγος, word).—That branch of pathological science which deals with the causation of disease.

AFFUSION.—A method of treatment which consists in pouring a fluid, usually water, either cold or warm, upon some part of the patient. See **BATHS**; and **WATER**, Therapeutics of.

AFRICA, SOUTH.—See **SOUTH AFRICA**.

AGEUSIA (ἀ, priv.; and γεῦσις, taste).—Loss of taste. See **TASTE**, Disorders of.

AGGLUTININS.—Substances causing the agglutination of bacteria. See **IMMUNITY**.

AGONY (ἀγών, strife or struggle).—Agony implies bodily pain or mental suffering so intense that it cannot be endured, but excites a struggle against it. It is also applied to the final struggle that may precede death.

AGORAPHOBIA (ἀγορά, a market-place, hence any open space; φόβος, fear).—**SYNON.** : **Fr.** *La peur des espaces*; **Ger.** *Platzangst*.—A morbid emotional state characterised by a feeling of fear at any open space. A person thus affected may be unable to cross a street or a square alone, or even in some cases to leave his room. It is accompanied by palpitation, tremblings, cold perspiration, a feeling of weakness in the legs, and sometimes by fainting. See **IMPERATIVE IDEAS**.

AGRAPHIA (ἀ, priv.; and γράφω, I write).—This term is applied to defects of intellectual expression by writing. These defects may occur alone, or in association with defects of speech, according to the extent and situation of the lesion. See **APHASIA**.

AGUE.—A popular synonym for malarial fever. See **MALARIA**.

AGUE-CAKE.—A form of enlargement of the spleen, resulting from the action of *Hamatozoon malariae*. See **SPLEEN**, Diseases of; and **MALARIA**.

AIKIN, In south-west division of South Carolina.—A mild, bracing, dry climate, said to resemble that of Mentone in warmth and dryness, but with larger monthly temperature-range. Soil, sandy. Recommended for pulmonary affections. See **CLIMATE**, Treatment of Disease by.

AINHUM (Nat., to saw).—This disease is peculiar to the dark-skinned races, being found not only among the inhabitants of tropical Africa, where it is very common, but also among the Hindoos, as well as among the negro population of America, especially of South America. At its commencement, a groove or furrow is seen at the base of the little toe (the part almost invariably attacked), situated on its inner and inferior aspect, and corresponding to the digito-plantar fold. The furrow soon extends to the entire circumference of the toe; and, as it becomes gradually deeper, the latter is left hanging by a slender pedicle, which can only be brought into view by separating the walls of the furrow. The distal portion swells into an ovoid mass, about twice its natural size; finally some accident snaps the pedicle, and the toe drops off in from four to ten years from the commencement of the disease.

The furrow is caused by a constricting band of hardened and contracted skin—a local scleroderma—which leads to faulty nutrition and degenerative changes in the parts beyond.

Ainhum is not a painful affection in itself, but the extreme mobility of the little toe causes trouble and inconvenience, for which patients often seek relief in amputation.

Occasionally the sides and bottom of the furrow ulcerate. Not infrequently both little toes are attacked by the disease; occasionally the other toes become similarly affected. Males are more subject to it than females. The microscope reveals only hypertrophy of the fibrous tissues at the seat of constriction, and atrophic and degenerative changes in the distal portion of the toe. The cause of ainhum is entirely obscure. Treatment by early division of the constricting band has been suggested.

PATRICK MANSON.

AIR, Therapeutic use of.—Atmospheric air is employed in the treatment of disease in many ways and for many purposes. The application to the body generally of air that has been warmed, or warmed and loaded with moisture, will be found described in the article on **BATHS**; while its administration to the respiratory organs, either in this form or as a vehicle for such substances as creasote, carbolic acid, alkaloids, and sulphurous acid, will be discussed under **INHALATIONS**.

GENERAL AËROTHERAPEUTICS.—The effects of compressed air on the body as a whole have been studied in the *air-bath*. This is a mechanical arrangement in the form of an iron chamber, which can be filled with air at any pressure, whether above or below the normal, by means of steam-power.

The principal physiological effects of air condensed by three-sevenths of an atmosphere were ascertained by von Vivenot to be:—Pallor of the skin and mucous membranes; a sensation of pressure in the ears;

diminished frequency of respiration, the act becoming easier; enlargement of the lungs and increase of the vital capacity; depression of the cardiac force, and diminution of the size and strength of the pulse; rise of temperature; increased vigour of muscular action, secretion, and nutrition generally; compression of the gaseous contents of the intestines; and, perhaps, increased absorption of oxygen and excretion of carbonic acid. When the pressure is excessive, dangerous or even fatal symptoms may supervene (see CAISSON DISEASE). Frequent exposure to condensed air will induce considerable increase of the vital capacity; and most of the other effects, both physical and chemical, will tend to persist. In a word, it may probably be said that the air-bath acts on the system, first, by increasing the general mechanical pressure; and, secondly, by admitting an increased amount of oxygen. In employing the air-bath, the patient is kept in it for a period of two hours, at first daily, but after some weeks less frequently. The pressure, which is employed in different cases at one-fifth to two-thirds of an atmosphere above the normal, must be slowly raised on admission, and reduced on removal of the patient.

Uses.—The number of diseases in which the air-bath may be employed is limited: (1) In certain forms of dyspnoea. It gives great relief in *spasmodic asthma*, and may also afford temporary relief in *emphysema*; but its prolonged use appears to be positively injurious, as it increases the pulmonary distension. (2) In hyperemia and *catarrh of the air-passages*, including pertussis. (3) In imperfect expansion or threatened retraction of the chest, as in the subjects of phthisis and chronic pleurisy. In these cases it is of doubtful service. Compressed air has also been extolled in some forms of cardiac disease, and in general malnutrition.

Artificially rarefied air is never employed in the form of the bath; but the natural supply in elevated regions has found favour as a means of treatment. See CLIMATE and PHTHISIS.

LOCAL AÉROTHERAPEUTICS.—When it is desired to bring compressed or rarefied air into contact with the *respiratory* surface only, other apparatus must be employed. Different forms have been in use for some years, respecting which it will be sufficient to state that the air contained in a portable gas-holder is compressed or rarefied by simple mechanical means, and thereafter brought into relation with the air-passages by an arrangement of tubes and valves. There are four possible methods of application: (1) inspiration of condensed air; (2) expiration into condensed air; (3) inspiration of rarefied air; and (4) expiration into rarefied air.

Another apparatus, called the *pneumatic cabinet*, has been introduced more recently. It consists of an air-bath, built of steel and glass, to accommodate both the patient and the administrator. The disturbance of pressure within the chest is effected by rarefying the air in the cabinet by means of a bellows, and then allowing the patient to inspire from the external atmosphere through a tube from without. This procedure is in effect mainly inspiration of a relatively condensed air.

The *physiological effects* of the several methods of application may now be briefly stated.

Inspiration of condensed air.—Inspiration of air that has been condensed by one sixtieth to one fortieth of an atmosphere produces a sensation of extreme distension of the chest, accompanied by an actual expansion of the thorax and lungs, and an

increased admission of air, so that inspiratory dyspnoea, if present, is relieved. At the same time the other thoracic contents are compressed, the systemic vessels fill, the arterial pressure rises, and the jugular veins become distended. The lungs and heart will be comparatively anæmic. If the application of condensed air be frequently repeated, the vital capacity, the size of the chest, and the respiratory force may all be increased, and partial relief may be permanently afforded to dyspnoea.

Expiration into condensed air is most difficult of accomplishment, and the effect on the circulation does not differ essentially from that just described.

Inspiration of rarefied air.—Inspiration of air that has been rarefied by one two-hundred-and-fortieth to one one-hundred-and-twentieth—or even, after a time, by one sixtieth—of an atmosphere, immediately causes the phenomena of inspiratory dyspnoea; the thoracic viscera are congested, and hæmoptysis may result, for the effect may be regarded as that of dry-cupping the pulmonary alveoli. The heart at the same time becomes full, and the jugular veins collapse.

Expiration into air that has been rarefied by one sixtieth of an atmosphere is attended with a sense of extreme compression of the thorax; at the same time there is actually a partial retraction of the lungs, an increase in the volume of expired air, and a corresponding diminution in the amount of residual air in the chest. Expiratory dyspnoea, if present, is relieved. While the lungs thus diminish in size, the other thoracic viscera are dilated—the heart and the pulmonary and other vessels within the chest being filled at the expense of those external to it, both arteries and veins. If the expiration into rarefied air be frequently repeated, the circumference of the chest will be diminished, while the vital capacity will be actually increased, along with increase of the inspiratory and expiratory force.

Uses.—The method of *inspiring condensed air* is obviously indicated in diseases where inspiratory dyspnoea is an urgent symptom. Spasmodic asthma, stenosis of the air-passages from anatomical causes, acute and chronic bronchitis, and atelectasis, have all been successfully treated by this method. In croup, where urgently indicated, it is most difficult or even impossible to employ it. In threatened phthisis it is used prophylactically, and in chronic phthisis it may usefully develop the healthy portions of lung; but it is contra-indicated in pyrexial cases, and may prove dangerous by inducing hæmoptysis. In chronic pleurisy it may prevent or remove the effects of collapse and retraction of the chest-wall. The inhalation of condensed air should also be of use in certain forms of cardiac dilatation, especially that due to mitral incompetence. Improving, as it does, the general nutrition, it may be combined with other remedies for anæmia. In the administration of condensed air, a 'sitting' should last from ten to thirty minutes, once a day—seldom twice.

Expiration into condensed air is not used therapeutically.

Inspiration of rarefied air may be regarded as a means of exercising the inspiratory muscles. Like the atmosphere of great altitudes, it may therefore be employed in persons with badly developed chests; and even in phthisis it may assist, by increasing the amount of blood in the lungs. In disease of the right side of the heart, it would assist the flow of blood from the veins into the lungs, but it is not likely to be employed for this purpose.

Expiration into rarefied air promises to be the most successful and most extensively employed of all the methods. In it, according to Waldenburg, we have the physical antidote for emphysema, and in his hands the majority of such patients are said to have been either cured or radically benefited. It has also afforded great relief in some cases of bronchitis, where it increases expectoration.

Other local applications of the physical properties of the air, as seen in aspiration, cupping, Junod's boot, and inflation, are described elsewhere in this work. See OXYGEN, Treatment by.

AIR-PASSAGES, Diseases of.—See RESPIRATORY ORGANS, Diseases of; also LARYNX, TRACHEA, and BRONCHI, Diseases of.

AIX-LA-CHAPELLE, Waters of.—Thermal sulphur waters. See MINERAL WATERS.

AIX-LES-BAINS, Waters of.—Thermal sulphur waters. See MINERAL WATERS.

AKINESIA (*ἀ*, priv.; and *κίνησις*, motion).—A synonym for paralysis of motion, whether partial or general. See PARALYSIS, MOTOR.

ALASSIO.—In Italy on the Mediterranean coast, between San Remo and Genoa. A mild bracing winter resort, sheltered by hills except on the south and east. Comparatively free from wind and dust. See CLIMATE, Treatment of Disease by.

ALBINISM (*albus*, white).—**SYNON.**: Congenital Leucoderma; Congenital Achroma; Albinismus.—**DEFINITION.**—A state of whiteness or absence of colour of the integument and certain other tissues, consequent on congenital absence of pigment and unaccompanied by structural cutaneous change. The want of colour may be *complete* or *incomplete*; *partial* or *universal*; *congenital* or *accidental*. Partial albinism may be limited to a spot of small dimensions; or there may be many such spots of variable extent, dispersed over the surface of the body, and giving rise to the appearance which is denominated *pie'd* or *piebald*; whereas in universal albinism the defect of pigment is not restricted to the integument, but is especially remarkable in the iris and choroid and the hair.

GENERAL CHARACTERS.—Persons affected with universal albinism are called *albinos*. It would seem more correct to limit the term 'albino' to those in whom the absence or defect of pigment is universal, and demonstrable not only in the integument but likewise in the eyeball. In the true albino, therefore, the skin is white or pinkish (when thin enough for its vessels to show through) and more or less transparent, and this both in the fairer and in the darker races of mankind; but in certain of the latter, where the pigmentary function is simply defective and not totally wanting, the colour of the skin may be grey, and more or less variegated and freckled. The long, soft, fine hair is of a pure silvery or white colour, may be diversely tinged, or may be red (Folker); and in some instances the whole body is covered with a white down. The iris is pinkish, in accordance with the density of its fibrous structure, and the consequent facility of penetration of the colour of its vascular layer; or, as generally happens in the negro, it is blue. The pupil is contracted and brightly red, from the

absence of the screen of protection usually afforded to the choroid membrane by its pigmentary layer; and for the same reason the rays of light penetrating the sclerotic and iris give a brilliancy of appearance to the fundus oculi. The absence of pigment in the eyeball is productive of several peculiarities of character in the albino. In the first place the excess of luminous rays penetrating the coats of the eyeball interferes with the correctness of vision; he stoops his head, or droops his eyelids, to shelter his eyes; he sees with more comfort in the dimness of evening than in sunlight; his vision is more or less imperfect; and nystagmus, nictitation, and photophobia are present in various degrees.

ÆTIOLOGY.—Certain animals, as rats, mice, ferrets, and some birds, are subject to albinism, and the affection may be met with in several members of the same family. Albinism is met with among all races of mankind and in every country, but is most common among those who are subjected to insalubrious conditions of climate and hygiene. For these reasons it is not uncommon among the natives of the marshy coast of Africa; among negroes who are transferred to unhealthy districts in South America and the West Indies; among the inhabitants of the western coast of South America and Mexico; in certain of the islands of the Indian Ocean; and even in the northern regions of Europe. When albinism is congenital, it has been assumed to be due to an arrest of development: but when accidental, its existence must be referred to exhaustion of chromatogenous or pigment-producing function. Albinos are usually mentally and bodily weak, but it is well known that albinism is often associated with perfect physical strength and intellectual vigour. Albinism exceptionally is hereditary. The usual sites of partial albinism are the mammæ, face, scalp, and genitals. The patches vary in size; their margins are well or ill defined; and they are asymmetrical, and on the non-pigmented areas the hairs are white. See PIGMENTARY DISEASES OF THE SKIN: (1) *Nævus Pigmentosus*.

TREATMENT.—Albinism baffles treatment.

JOHN HAROLD.

ALBUMENS.—**DEFINITION.**—Albumens are substances closely resembling egg-albumen, the chief constituent of white of egg or albumen. To distinguish between the white of egg and its chief constituent, the latter is sometimes spelt *albumin*. Albumens constitute a subdivision of the class of albuminous bodies, which includes all substances having a general resemblance to albumen. See ALBUMOSES.

ENUMERATION.—The sub-class properly contains only two members, *egg-albumen* and *serum-albumen*; but the name *Bence-Jones's albumen* has been given to an albuminous body differing very considerably in its properties from the other two.

CHARACTERS.—Egg-albumen and serum-albumen are semi-transparent, yellowish, and structureless when dried. They are soluble in water; and this solution is coagulated by boiling. From the same solution they are precipitated by: (a) nitric acid; (b) salts of the heavy metals, for example, copper-sulphate; (c) acetic acid with potassium-ferrocyanide; (d) boiling with acetic acid and a neutral salt, for example, potassium-sulphate; (e) alcohol. Egg-albumen is distinguished from serum-albumen by the coagulum which it forms with nitric acid being insoluble in excess, while that of serum-

albumen is soluble. Bence-Jones's albumen gives no precipitate with excess of nitric acid unless left to stand, or unless heated and left to cool, when it forms a solid coagulum. This coagulum redissolves on heating, and again forms on cooling. It is therefore an albumose (see ALBUMOSES). It may be separated from ordinary albumen by adding nitric acid, boiling, and filtering when hot. The ordinary albumen will remain on the filter while Bence-Jones's albumen will pass through, and will coagulate when the filtrate cools.

MODIFICATIONS.—By the action of acids and alkalis albumen may be converted into *acid-albumen* and *alkali-albumen* respectively, neither of which is coagulated by boiling.

Acid-albumen may be formed in two ways: First, by dissolving solid albumen in concentrated nitric or other mineral acid with the aid of heat. Secondly, by heating an aqueous solution of albumen with one of these acids very much diluted (1 in 500). Although soluble in very concentrated or very dilute acids, acid-albumen is insoluble in moderately dilute acids. Therefore when the solution in concentrated nitric acid is diluted with water, a precipitate is formed, which redissolves when much water is added. And, conversely, when acid-albumen is made by boiling a solution of albumen in water with very dilute nitric acid, the addition of more acid will throw down a precipitate, which redissolves if a very large excess of the concentrated acid be added, and especially if it be heated at the same time. On neutralising a solution of acid-albumen, a precipitate is thrown down, which dissolves very readily in excess of alkali.

Alkali-albumen, or *alkali-albuminate* as it is also called, is formed by dissolving albumen in caustic potash or soda; or by adding either of these to its aqueous solution and allowing this to stand, or heating it. This modification is not precipitated by heat, but is precipitated by neutralisation; the precipitate dissolving very readily in slight excess of acid. If alkaline phosphates are present in the solution, as they are in urine, alkali-albumen requires a slight excess of acid to throw it down, and is not precipitated by exact neutralisation, as acid-albumen would be under similar circumstances.

T. LAUDER BRUNTON.

ALBUMINOID DISEASE.—See AMYLOID DISEASE.

ALBUMINURIA.—**DEFINITION.**—A condition characterised by the presence of albumen in the urine. Other albuminous bodies, not albumens, may be present in albumosuria, hæmoglobinuria, hæmaturia, peptonuria, pyuria, and spermatorrhœa.

SYMPTOMS.—Albumen may occur in the urine without any symptoms whatever, but its continuous loss leads to anæmia and changes in the circulation, which usually originate a series of symptoms. These are: a pallid pasty complexion, dry skin, and tendency to œdema of the cellular tissue, noticeable on the eyelids and ankles; derangement of digestion, flatulence, occasional nausea, and irregularity of the bowels; nervous disorder, shown by muscular weakness, languor, lassitude, vague pains about the loins, and headache; calls to make water during the night; attacks of difficult breathing; palpitation, and frequently accentuation of the second sound of the heart over the aortic cartilage, and reduplication of the first sound over the septum ventriculorum.

TESTS FOR ALBUMEN.—The two tests usually employed to detect albumen in the urine are—first, boiling; and, secondly, the addition of nitric acid; both of which produce a cloud or precipitate. If the urine is turbid, the albuminous cloud may not be noticed; and therefore such urine should be filtered before the application of either test, unless the turbidity, being dependent on the presence of urates, is removed by heat cautiously applied.

Method of employing the test by boiling.—With the object of saving time the urine is often boiled at once, but the results thus obtained are liable to several fallacies, which will be subsequently described. In order to avoid such fallacies the following method should be pursued:—Ascertain the reaction of the urine; and if it be alkaline or very strongly acid, add acetic acid in the one case, or liquor potassæ in the other, until its reaction is only slightly acid. Fill a test-tube to about one-third of its capacity with the urine, and hold it obliquely in the flame of a spirit-lamp, in such a manner as to heat the upper part of the fluid only, until it boils. If it be turbid from urates, it should be first warmed throughout until it becomes clear, and then the upper part only should be boiled. Finally, add a drop or two of acetic or nitric acid.

If albumen be present, it will form a cloud or a coagulum, more or less dense according to its amount. When there is much albumen, its quantity may be roughly estimated by allowing the boiled urine to stand for a definite number of hours, so that the coagulum may subside, and then observing whether it forms a fourth, a third, or a half of the whole length of urine in the test-tube. A small quantity causes a cloud, but no distinct coagulum; and, if merely a trace be present, a faint haze only will be observed, which is best seen by looking through the test-tube at a dark object. The advantage of heating the upper part only of the urine is, that the lower portion, which remains clear, affords a standard by comparison with which a faint cloud in the heated part may be more readily detected.

Fallacies of the test by boiling.—The first fallacy is that albumen may be present, and yet no cloud or coagulum be produced on boiling. This may occur if the urine be alkaline or very strongly acid, because alkali-albumen or acid-albumen, which are soluble in water, may be formed. It is to prevent the formation of *alkali-albumen* that acetic or nitric acid should be added to alkaline urine before boiling. This addition of acid also causes the coagulum to separate more readily; and it should therefore be made when the urine is neutral. On the other hand, urine rarely or never contains sufficient acid to form *acid-albumen*, unless the patient has been taking mineral acids; and therefore the addition of liquor potassæ is not necessary except under these circumstances. The second fallacy of the test by boiling is, that a cloud resembling that of albumen may be produced, although the urine is free from this substance. This occurs when the acidity of the urine is too slight to hold the earthy phosphates in solution, the heat probably affecting the relation between the basic and acid phosphates which are normally in solution, whereby deposition of insoluble phosphate results, forming a cloud like that of albumen. The two clouds are readily distinguished by the addition of a drop or two of acetic or of nitric acid, when if due to phosphates the cloud will disappear by solution, but if caused by albumen it will remain. If an excessive quantity of nitric acid

be added, an albuminous cloud may also clear up; for albumen coagulated by heat is soluble in strong acid, though only to a slight extent.

Application of the nitric acid test.—Pour some urine into a test-tube, and then allow about one-fourth of its bulk of strong colourless nitric acid to trickle slowly down the side of the tube, so as to form a layer below the urine without mixing. Or the acid may be put in the test-tube first, and the urine poured on it. Both processes give the same result. If albumen be present, a haze or cloud will form close to the line where the liquids meet.

Fallacies of the nitric acid test.—1. Albumen may be present and yet escape detection, if the nitric acid is simply poured into the urine and mixed with it, as is sometimes done. For if there be too much or too little acid, acid-albumen is formed and dissolved; whereas, if the liquids form two distinct layers, as in the process already described, the acid gradually mixes with and shades off into the urine, so that, at a greater or less distance from the line where they join, it is certain to be of the proper strength to precipitate the albumen. 2. Albumen may be supposed to be present when it is not, from the formation of a cloud by the precipitation of acid urates. This cloud disappears on the application of heat; and another specimen of the urine tested by boiling gives no cloud. To avoid this fallacy, it is common to employ the test by boiling, in addition to that by nitric acid. 3. The third fallacy is not of common occurrence. It is due to the presence of fat or saponified fats in the urine. Urine containing these when simply boiled gives no cloud; but if nitric acid is added to it in the cold, or acetic acid when it is hot, the fatty acids are precipitated and form a cloud resembling albumen. This is distinguished by not being formed if along with dilute acetic acid some ether is added to the urine before boiling; the ether retaining the fatty acids in solution. If the precipitate produced by nitric acid be collected on a filter, and treated with ether, it will be dissolved, while an albuminous precipitate will not. Copaliba, which can be recognised by its odour, sometimes causes an opalescence in the urine, which is increased by nitric acid, but is removed by heat.

Additional tests for albumen.—When urine contains *mucus*, which would render the presence of an albuminous cloud obscure, a solution of ferrocyanide of potassium followed by acetic acid should be added: this will produce a cloud if albumen be present, whilst it rather clears up a turbidity due to mucus. It has a similar action on nucleins. The terms nucleins and nucleo-albumens have been given of late to the substances formerly known as mucins. In the opinion of the writer this is unadvisable because it tends to direct attention away from the fact that these substances bear the same relation to the mucous membranes of the urinary passages that mucous excretion does to the mucous membrane of the respiratory passages. A solution of pyrophosphate of sodium also precipitates albumen. A strong solution of trichloroacetic acid also gives a precipitate with albumen. If a few drops of albuminous urine be poured into a test-tube containing one or two drachms of a saturated solution of picric acid, a precipitate is formed which does not dissolve on boiling, and thus differs from that due to albumoses. This test can therefore be used like the succeeding one for albumoses as well as albumens. Alkaloids in the urine also give a precipitate with picric acid which clears up with heat and reappears on cooling, so that

in the case of patients taking quinine, caffeine, &c., this source of fallacy requires to be kept in mind. A concentrated solution of salicyl-sulphonic acid has been used both as a test for albumen and as a method of distinguishing serum-albumen from albumoses and peptone. With all these substances this reagent added to an acid urine gives a turbidity or precipitate. If the urine is not acid it must be previously acidulated with acetic acid. Should albumoses or peptone only be present, the precipitate disappears on boiling and recurs on cooling. If albumen also be present, the precipitate simply becomes less on heating and again becomes denser on cooling. These tests are sometimes useful in determining the presence of albumen in the urine in doubtful cases.

QUANTITATIVE ESTIMATION OF ALBUMEN.—There are three methods in common use for this purpose. The first is easy but inexact. It consists in boiling the urine with dilute acetic acid in a test-tube, allowing the coagulum to subside for a definite number of hours, and then estimating the proportion it bears to the quantity of urine boiled—for example, a fourth, a third, &c. The second is the most exact, but is troublesome. It is like the first; but the urine is carefully measured before boiling, and the amount of coagulum is ascertained by collecting it on a weighed filter, washing, drying, and again weighing it. The third method is easy and tolerably exact. A tube of known length is filled with urine and placed in a polarising apparatus. From the amount of rotation which the polarised ray undergoes in passing through the urine, the amount of albumen it contains may be calculated. A fourth method was recommended by Roberts. It consists in diluting the urine with water until it gives a haze on the addition of nitric acid, which does not become visible until between one half and three quarters of a minute after the acid has been added. This dilute urine contains 0.0034 per cent., or 0.0148 grain of albumen per fluid ounce; and from the degree of dilution required the amount contained in the urine may be calculated. A fifth method is that of Esbach. It is less accurate than Roberts's, but is convenient. It consists in precipitating the albumen from urine in a graduated tube by means of picric acid, and reading off the quantity of albumen precipitated after the tube has stood for twenty-four hours. The precipitant consists of 1 part of pure picric acid and 2 parts of citric acid in 100 parts of water. The tube is filled up to a mark with the urine, and about two thirds of its bulk of the precipitant is then added; the exact amount necessary being indicated by another mark on the tube. The lower part of the tube is graduated with lines numbered $\frac{1}{2}$ up to 7, and these indicate the parts by weight of albumen in 1,000 parts of urine by measure. Thus if the upper level of the precipitate after twenty-four hours stood at 2, the proportion of albumen would be 2 in 1,000, or $\frac{1}{500}$ of a grain of dry albumen to the ounce of urine. The results given are rather too low, and the method gives the best results when the proportion of albumen is small, so that urines containing much ought to be diluted before the test is applied. It is unsuitable if quinine, antipyrin, or thallin is likely to be present in the urine.

PATHOLOGY.—Albuminuria has been divided by some authors according to the sources of the albumen. When the albumen has come from the kidneys, it has been called true albuminuria, and false when it is derived from some other part of the

urinary passages. As diagnosis has improved, this classification is less employed and the terms true albuminuria and false albuminuria are now used to denote different forms of albumen, the albuminous body, in each case, passing through the kidney. Albuminuria has been said to occur in consequence of various conditions: e.g. changes in the blood, changes in the circulation, changes in the kidney. Thus abstinence from salt, or a diet of eggs alone, is said to produce albuminuria by altering the constitution of the blood; and an alteration in this fluid is supposed to be partly the cause of the albuminuria observed in high fevers, scarlatina, diphtheria, and osteo-malacia. The albuminuria of heart-disease depends on changes in the circulation; and that of nephritis on alterations in the kidney. In order to distinguish more clearly between the different kinds of albuminuria we may divide them into—(1) *false albuminuria*, in which some other albuminous body than serum-albumen is present; (2) *true albuminuria*, in which serum-albumen, frequently accompanied by globulin, appears in the urine. In *true albuminuria* there is always some change either in the circulation through the kidney, or in the structure of the kidney itself. In *false albuminuria* the albuminous body passes out through the kidney, without there being any alteration either in its circulation or structure.

(1) *False albuminuria*.—The chief albuminous bodies occurring in false albuminuria are hæmoglobin, egg-albumen, globulin, and Bence-Jones's albumen (albumose). Hæmoglobin occurs in the urine whenever blood is present in it (see HÆMATURIA), in which case it is contained in the corpuscles; or it may occur free (see HÆMOGLOBINURIA), the blood-corpuscles, while still circulating in the vessels, having undergone solution. This may result from the inhalation of arseniuretted hydrogen, or from the introduction of bile-acids or of a large quantity of water into the veins. Hæmoglobin is also found in the urine in paroxysmal hæmoglobinuria, but the cause of the solution of blood-corpuscles in this disease is unknown. Egg-albumen is excreted by the kidneys, and appears in the urine, whenever it is injected directly into the circulation or under the skin, or when it is absorbed unchanged from the stomach or rectum. When taken into the stomach it is usually completely digested before it undergoes absorption; but when taken in such large quantities that the whole of it cannot be digested, part of it is absorbed unchanged and is excreted in the urine. Thus a diet consisting exclusively of eggs, especially when continued for several days, produces false albuminuria, and large enemata of eggs have a similar effect in animals, and probably also in man. Bence-Jones's albumen is of very rare occurrence. It is found in osteo-malacia. Like egg-albumen, it is excreted by the kidneys when it is injected into the circulation, or in large quantities into the intestine. It is almost, if not quite, identical with the hetero-albumose which Kühne finds to be one of the products of imperfect digestion. It seems probable that those cases of albuminuria which appear to depend on imperfect digestion are due to the passage into the systemic circulation of albuminous bodies, which have not undergone the proper transformation in the alimentary canal or liver. See ALBUMOSES; ALBUMOSURIA; GLOBULINURIA.

(2) *True albuminuria*.—In true albuminuria there must be some change either in the circulation

or structure of the kidney, for serum-albumen differs from the other albuminous bodies just mentioned in not being excreted by the healthy kidney. Some regard the alterations in the circulation which produce albuminuria as of two kinds:—(a) increased pressure of blood in the renal arteries; (b) increased pressure in the renal veins. Increased pressure in the arteries may depend either on general high arterial tension, or on an increased local supply of blood to the kidney, owing to dilatation of the renal arteries, such as follows division of their vaso-motor nerves. Experiments seem to show, however, that increased tension in the renal arteries does not produce albuminuria, and that the only change in circulation which will cause it is increased pressure in the renal veins. Congestion of the renal veins may be produced by ligature of the renal arteries; and when the flow of blood through the kidney is temporarily arrested by ligature of the artery, the urine secreted after the removal of the ligature is albuminous. Venous congestion of the kidney also occurs whenever the onward flow of venous blood is obstructed, either by a ligature on the renal veins; by thrombosis of the renal veins or of the inferior vena cava above them; by the pressure of a tumour or of the pregnant uterus upon them or the vena cava; by disease of the liver obstructing the vena cava; or by disease of the heart or lungs, such as tricuspid or mitral regurgitation, or chronic bronchitis and emphysema. The temporary albuminuria sometimes observed after cold bathing may also be due to venous congestion; and it is probable that albuminuria consequent upon lesions of the nervous system is due rather to the changes which these produce in the circulation than to any direct action of the nerves upon the tissues of the kidney itself. The albuminuria observed after varnishing the skin is due either to the chill produced by the cutaneous vascular dilatation caused by the varnishing, or possibly in part to the production or the retention of some substance which acts as a poison. The structural changes in the kidney which cause albuminuria are acute and chronic inflammation, amyloid degeneration, and cirrhosis. See KIDNEYS, Diseases of.

FORMS OF ALBUMINURIA. A good many cases of albuminuria are more or less intermittent. They may be intermittent in the sense that they last only for a certain part of the day and then disappear, or that they may last for several days, weeks, or even months together, and then disappear for a prolonged period. Among the intermittent albuminurias which last for a short time are those which come on after exertion. It has been noted, especially in Germany, that after soldiers have marched for some distance a number of them exhibit albumen in the urine, although in every other respect the men appear to be perfectly healthy. The same thing has been noted as consequent upon violent exertion among athletes after playing heavy games, or after long walks or severe climbs. It is noted also after violent exertion due to pathological causes, e.g. after an epileptic fit, where all the muscles have been in violent contraction. Exertion of any kind tends to raise the blood-pressure, and probably the appearance of albumen in the urine in these cases has been due to some disturbance of the circulation. Blood-pressure is also raised by exposure to heat. Heat as a rule dilates the peripheral vessels and allows the blood to flow more rapidly through, so that the blood-pressure should, accordingly, fall;

but the dilatation of the peripheral vessels seems to be more than compensated by the increased rapidity and increased force of the cardiac beats ; so that the blood-pressure rises instead of falling. After exposure to great heat, whether it be external heat, as in various trades, or to the sun in hot climates, or heat generated in the body, as in infective fevers, a certain amount of albumen is apt to appear in the urine.

How far the albuminuria in such cases is due to general venous congestion during the exertion it is difficult to say. In the case of infective fevers local changes produced in the renal capillaries by the infecting microbes probably play a great part in the production of albuminuria. In cases of renal calculus, albuminuria also follows exertion and may be accompanied by hæmaturia. It comes on after passive movement, such as jolting in a carriage or railway train, as well as after active exercise, such as walking or riding. It is generally, but not invariably, accompanied by pain in the lumbar region.

Infarct in the kidney, in cases of cardiac disease or atheroma, may give rise to temporary hæmaturia and albuminuria. In poisoning by mercury, the tubules of the kidney have been found stopped up by plugs of carbonate of lime. It would almost seem as if the mercury had displaced carbonate of lime from the bones and caused it to form plugs in the tubules. Possibly this may be the cause of a form of temporary albuminuria, which has been noticed by the writer in men who had gone through a mercurial cure for syphilis and in whose urine albumen was found when they subsequently tried to insure their lives. Such cases sometimes recover under a course of iodide of potassium. Albumen occurs very frequently in the urine of young men and is known as the albuminuria of adolescence. The pathology of this form of albuminuria is not well understood, but it frequently occurs after a seminal emission, and is probably due to the close connection between the spinal centres of the kidneys and of the genital organs. If the urine, in such cases, be examined a day or two after any genital excitement has passed off, it may be found free from albumen. The albuminuria of adolescence is probably closely associated with the albuminuria of posture, which rarely or never occurs in adult men, but only in adolescents or children. It disappears completely when the individual is kept on his back, but reappears when he is upright. In this it resembles the œdema of cardiac disease, severe æmæmia, and chlorosis, and it is probably due to laxity of the renal vessels, or to some alteration in their permeability, such as occurs in chlorosis.

Another form of intermittent albuminuria is that due to digestion. It comes on after a meal, while the products of digestion are being absorbed. It is probably due to some imperfection in the digestive process.

DIAGNOSIS OF ALBUMINURIA.—Admixture with blood, or pus, or semen, or prostatic mucus, may give rise to the presence of albumen, but if no more is present than can be accounted for by their admixture, it is probable that the kidneys themselves are healthy. The persistent presence of albuminuria with casts points to the existence of some form of renal disease, for the diagnosis of which see **KIDNEYS, Diseases of**. At the same time the writer has seen cases in which albumen, sometimes in considerable quantities, was constantly present for years, the patient being, to all appearance, in perfect health.

Albuminuria in Life Assurance.—When albuminuria is definitely ascertained to be dependent upon some organic form of kidney disease, the life is always uncertain, and if taken at all can only be taken under very heavy extra payment. One of the chief difficulties in taking such lives even if the premiums are to be paid within a limited period is their uncertainty. Persons suffering from chronic nephritis, either tubular or interstitial, may continue under favourable conditions to live for many years, but at the same time a sudden chill, or intemperance in eating or drinking, or an intercurrent attack of some infective disease may carry them off in a few days. In waxy kidney the probability is that the life will not be prolonged more than ten years. The subject of albuminuria occurring in persons apparently healthy was investigated for the United States Life Assurance Company in 1877, 1878, and 1879 for the purpose of ascertaining the subsequent health and longevity of those who had exhibited this condition when examined for life assurance. Albuminuria was found in from 10 per cent. to 12 per cent. of those who presented themselves for examination presumably in perfect health. According to the writer's experience this is a very much larger proportion than is found in this country, for out of 150 consecutive persons who presented themselves for examination only four had albuminuria, or a little under 3 per cent. The total percentage of deaths in the Mutual Life Insurance Company of New York in 1875 was also a little under 3 per cent. The health of all those who had albuminuria, although apparently sound when examined, tended to deteriorate, and their lives were shorter than the usual expectation of healthy persons. The experience of men who have extensive experience in examining candidates for posts abroad is that however healthy the young men may seem, the presence of even transient albuminuria renders them less fitted for foreign service, less energetic, and less likely to retain their health than those who are free from such an affection.

TREATMENT.—(1) In *false* albuminuria, where hæmoglobin appears in the urine, the treatment indicated is to counteract the solution of blood-corpuscles ; and for this purpose quinine is very often useful. When other kinds of albumen appear in the urine, and are probably due to imperfect digestion, the treatment is to give some artificial digestive fluid. Arsenic is also useful. Regarding those cases of osteo-malacia in which Bence-Jones's albumen occurs, we unfortunately know very little.

(2) In *true* albuminuria, depending on venous congestion, the obstacle to free circulation should be removed if possible, and the congestion lessened, both by drawing the blood from the interior to the surface of the body, and by causing contraction of the renal vessels. The blood may be drawn from the interior to the surface by means of warm baths ; but in some cases these prove injurious rather than useful, and the employment of a wet pack, which has a similar effect on the distribution of blood without exciting the heart, is to be preferred. Cupping over the loins is serviceable : it probably acts by causing reflex contraction of the renal vessels rather than by actually draining blood away from them. The tone of the renal vessels may be increased by the employment of digitalis (see **DIURETICS**) ; and this drug is useful even when no cardiac disease is present, although its good effects are still more marked when the congestion is dependent on disease of the heart. The constant drain

of albumen from the body occasions anæmia, which not only produces many unpleasant symptoms, but tends to cause fatty degeneration of various organs, from which there is no reason to believe that the kidneys are exempt. The administration of iron, therefore, is the chief medicinal remedy in structural disease of the kidneys. It is useful by diminishing or removing the symptoms of anæmia, and the tendency to fatty degeneration consequent thereon; and also by increasing the tone of the vessels, thus diminishing the loss of albumen.

T. LAUDER BRUNTON.

ALBUMOSES.—**DEFINITION.**—Albumoses are proteid bodies derived by the action of digestive ferments (pepsin chiefly) upon albumens and globulins, and in their properties may be classed as intermediate between these proteids and the final product of digestion (peptone). They are formed during natural digestion in the stomach and also in artificial digestion.

ENUMERATION.—Many varieties of albumoses have been described, collectively termed *protooses*. The individual bodies differ somewhat, according as they are formed from albumens (albumoses) or globulins (globuloses): for all practical purposes the term albumose is the best to use. The forms of albumose important in medicine are *hetero-albumose*, *proto-albumose*, and *deutero-albumose*, the last being closely allied to peptone.

CHARACTERS.—**I.** *Hetero-albumose* ('Bence-Jones's albumen') is insoluble in water, but soluble in dilute saline solutions, from which it is precipitated by heat if no free acid is present. In some cases it is precipitated at a temperature of 43° to 50° C., and re-dissolves on heating the liquid to the boiling point. Artificially prepared hetero-albumose is rendered partly insoluble by heating; but the coagulum is soluble in dilute acids and alkalis, thus distinguishing it from the coagulum formed on heating a solution of serum-albumen or serum-globulin. Hetero-albumose is also precipitated from solution by saturation with magnesium sulphate or sodium chloride.

2. *Proto-albumose* and *deutero-albumose* are soluble in water, are not precipitated by heat, and are thus sharply distinguished from hetero-albumose.

These three albumoses have one reaction in common (besides those given by all proteids), viz. that with a trace of copper sulphate and an excess of liquor potassæ they give a pink-red colour (biuret reaction), the colour given by hetero-albumose being the least marked. They all behave in a peculiar way to nitric acid: if added drop by drop to a solution of hetero- or proto-albumose, nitric acid causes a precipitate, which is soluble in excess of the acid, but is also soluble on heating, re-appearing on cooling, and so on. With deutero-albumose, however, nitric acid causes no precipitate, unless common salt be added until the liquid is nearly saturated with it: the precipitate which is then produced by the acid behaves like the nitric-acid precipitates of proto- and hetero-albumose. (For other distinctive reactions see ALBUMOSURIA.) Albumoses are distinguished from peptones by the nitric-acid reaction; as well as by their precipitation with acetic acid and potassium ferro-cyanide, and with neutral ammonium sulphate added to saturation. The characters of true peptones are that they are not precipitated by heat, by nitric acid under any condition, by acetic acid and potassium ferro-cyanide, or by saturation

with neutral ammonium sulphate. This last test is the most distinctive. In the presence of ammonium sulphate to saturation they give the biuret reaction, and are thrown down by tannin.

SIDNEY MARTIN.

ALBUMOSURIA.—**SYNON.** : Propeptonuria.

DEFINITION.—A condition in which albumoses are present in the urine. The condition where peptones are present (peptonuria) is not at present distinguishable from albumosuria. Peptonuria will therefore be considered under this heading.

TESTS FOR ALBUMOSE OR PEPTONE IN URINE.—Urine containing albumoses or peptones shows ordinarily no special characteristics indicating their presence; except, in some cases, frothing when shaken. It may be dark- or light-coloured, of high or low specific gravity, and with or without deposit. In one case Kühne found a whitish deposit, consisting partly of albumose; and in a similar case Bence-Jones found casts, ordinary albumen being absent. As a rule, however, albumose and peptone are present in solution in the urine. In searching for these, coagulable albumen must be absent, or if present removed by filtration after coagulation. The following methods are, therefore, to be used: Heat the top of the column of urine in a test-tube in the usual way, but without the addition of acid. If a cloudiness appears, it is due to the precipitation of coagulable albumen, of phosphates, or of hetero-albumose (Bence-Jones's albumen). Continue the heating to the boiling-point; the cloudiness, if due to hetero-albumose, will clear up, that due to phosphates and albumen will remain. A precipitate in urine, then, caused by a moderate heat and redissolving on boiling, is hetero-albumose. This may be verified by determining the exact temperature at which the precipitation occurs: hetero-albumose is precipitated between 43° and 50° C. (109.4° and 122° F.), serum-albumen or globulin at 73° – 75° C. (163.4° and 167° F.), and phosphates only when near the boiling-point; this last precipitate also redissolves on cooling. If the urine contains albumen or globulin, it must be boiled after the addition of a drop of acetic acid, and filtered. The filtered urine must then be tested for albumose in the way to be described. The presence of hetero-albumose is indicated by the test last mentioned; in addition, it gives a characteristic nitric-acid test. If to the cold urine nitric acid be added drop by drop, a precipitate forms which dissolves on heating, re-appears on cooling, redissolves on heating, and so on: this is perfectly characteristic of the body, since the similar precipitate of albumen or globulin does not redissolve on heating. By neither of these reactions is deutero-albumose or peptone indicated, and urines containing these two bodies (one or both of them) are those usually classed as examples of 'peptonuria.' Their presence is shown by the following tests, which must be applied after hetero-albumose has been shown to be absent, and after coagulable albumen has been removed:—(a) A drop of dilute solution of copper sulphate added to the urine, followed by an excess of liquor potassæ, causes a pinkish-red coloration (biuret reaction); or a drop of diluted Fehling's solution may be added to the urine, and then an excess of liquor potassæ if necessary. If the deutero-albumose and peptone are present in small quantity, this reaction is not obtained. (b) The urine is added drop by drop to

a saturated solution of picric acid; both deuto-albumose and peptone are precipitated, and are redissolved on heating, thus distinguishing them from mucin and from albumen.

The only accurate way of distinguishing deuto-albumose from peptone is to shake the clear urine in a test-tube with solid neutral ammonium sulphate. If the urine gives the two tests just described, and gives a precipitate with ammonium sulphate, it contains deuto-albumose. If it gives the tests and no precipitate with the salt, it contains peptone, and the case is one of true peptonuria. It is best, in applying these tests, to evaporate the urine to a small bulk.

Proto-albumose has not as yet been found in urine.

Quantitative Estimation. This is of but little clinical value. It may be done by precipitating a measured quantity of urine with a large excess (ten times its bulk) of alcohol, collecting, drying, and weighing the precipitate.

PATHOLOGY.—The presence of albumoses and peptones in the urine is a pathological, not a physiological, phenomenon. These bodies are formed during normal digestion by pepsin and hydrochloric acid in the stomach, and peptones are also formed in pancreatic digestion. But although they are thus formed in the gastro-intestinal canal, they are not found in the absorbent vessels of the stomach and intestine in any appreciable quantity; neither in the veins nor in the chyle-vessels. In the general systemic veins and lymphatics they are not present; and their occurrence in arterial blood in small quantities is extremely doubtful. Lastly, they are not present in the living tissues, nor in the fluids which bathe them. If they are found in the urine, they are therefore either derived from the gastro-intestinal canal, or are formed from some pathological condition in the tissues, or perhaps in the blood. With regard to their first source, it is quite reasonable to suppose that the metamorphosis (probably into serum-albumen) which albumoses and peptones normally undergo when passing through the intestinal wall, may not take place in certain diseases where absorption is deficient, and that they may thus pass into the circulation, and be excreted by the kidneys in the urine. This, however, is a mere conjecture to explain the occurrence of 'peptonuria' (albumosuria) in some cases of chronic dyspepsia with dilated stomach. The second source of the origin of albumoses and peptones in the body is a complicated one. If these bodies are formed in any organ, tissue, or fluid of the body, they are absorbed into the blood, and then find their way into the urine. It is known that if albumoses or peptones are injected into the blood of an animal they are excreted in the urine; that hetero- and proto-albumose pass out in the urine mainly as deuto-albumose; that deuto-albumose passes out chiefly as peptone; and that peptone is unchanged as it passes from the blood into the urine. The same facts probably hold good for the human organism.

Bence-Jones's albumen (hetero-albumose) was first found in the urine of a case of osteo-malacia; and Virchow found a similar body in the diseased bones. This, then, is a clear case of excretion of the albumose from the diseased part, the excretion of a proteid which is outside the normal proteid-metabolism of the body. A similar albumose has also been found in a case, not of osteo-malacia, but of glycosuria (Gowers). In the case of all abscesses, whether

acute or chronic, in empyema and purulent peritonitis, albumoses (or peptones) are found in the urine. Here the explanation is simple, since the pus contains albumoses, and these are simply excreted by the urine after absorption into the blood. In the case of abscesses and of osteo-malacia there are collections of cells which undergo disintegration, the proteids of the cells (consisting almost solely of coagulable albumen and globulin) becoming partly transformed into albumoses. This transformation takes place by the agency of bacteria present in the pus, but it may also possibly be due to a digestive ferment set free by the dying cell. This action of bacteria with the disintegration and gradual death of exuded cells, and the formation of albumoses, probably explains the occurrence of albumosuria and peptonuria in phthisis, in pneumonia, in epidemic cerebro-spinal meningitis, in cases of cancer and other malignant growths, in the puerperal state, in typhoid fever, and in organic liver-disease. In phosphorus-poisoning there is also great disintegration of many tissues and organs, and albumosuria (peptonuria) occurs; in scurvy also and acute infectious diseases (especially measles) it is sometimes present.

One form of peptonuria has been ascribed to an origin in the kidney-cells in cases of chronic nephritis, where some of the coagulable albumen which is being continually excreted is changed into albumose or peptone. Peptonuria may indeed alternate with albuminuria in these cases, and peptone may be present as well as albumen. Peptonuria with albuminuria is not uncommon in advanced chronic phthisis. Albumose and peptone are also found in the urine in many other conditions, in which no explanation of their presence is evident; such as many inflammatory eruptions of the skin, pemphigus, urticaria, and nervous diseases—cerebral hemiplegia or psychoses.

SYMPTOMS.—From the account given of the pathology of albumosuria and peptonuria, it will be seen that they are only to be regarded as symptomatic of other graver pathological conditions; and no symptoms can be very directly ascribed to the presence of albumoses and peptones in the body, as associated with the diseases which have been already enumerated. But there are certain physiological effects of these proteids which are important to recollect. When injected into the circulation of a dog, albumoses (and peptones to a less extent) markedly reduce the blood-pressure, and produce coma and death, while the blood remains uncoagulated for a long time after death. These effects are not necessarily associated with, or threatened by, the presence of albumosuria in man; possibly because the amount of albumose present in the blood at one time is never sufficient to produce them. When such appearances as coma and uncoagulated blood after death are observed in the diseases already enumerated, they are ascribed either to the result of the grave lesion on the body generally, or the brain in particular, or to the retained chemical products of tissue-disintegration. Albumoses and peptones form one group of these toxic products, aiding the production of coma and of *post-mortem* fluidity of the blood.

Another physiological effect of albumoses is that of producing fever when injected into the circulatory system. The fever is to some extent proportional to the dose, and is produced even when the dose is insufficient to cause coma and fall of blood-

pressure, and in animals (such as rabbits) whose circulation and cerebrum are not affected by the poison. The fever of infective disease is partly due to the absorption of these albumoses.

According to our present knowledge, it may be said that the chief clinical significance of a large amount of peptone or albumose in the urine is an extensive cell- (and proteid-) disintegration in the body or some infective process. SIDNEY MARTIN.

ALCOHOL.—SYNON. : Ethyl-Alcohol ; Vinic Alcohol ; Spirit of Wine. (C_2H_5O .)

Alcohol is the product of a process of fermentation induced by the action of a microscopic fungus, *yeast*, upon certain kinds of sugar, especially grape-sugar, but also upon milk-sugar and that derived from the different varieties of starch. In this process a peculiar metamorphosis takes place, by which alcohol and carbon dioxide are produced in considerable amount, together with very minute quantities of succinic acid, glycerine, and other bodies.

The discovery that the ferment by which the sugar is decomposed into alcohol and carbon dioxide is formed by a living cell was made simultaneously in 1836 by Th. Schwann in Germany, and by Cagniard-Latour in France.

Alcohol may also be produced synthetically from its elements—carbon, hydrogen, and oxygen.

As alcohol is very volatile, boiling at 172° F. (78° C.), it may be separated by distillation from the water with which it is at first combined. Other means must be resorted to, however, in order to separate the ultimate parts of this water, as a strong attraction exists between the two liquids.

Alcohol, diluted with about 95 per cent. of water, and subjected to the action of another microscopic fungus, is oxidised into aldehyde and further into acetic acid.

PHYSIOLOGICAL EFFECTS.—Applied to the skin, alcohol produces a sensation of coolness, due to its rapid evaporation, but, if the application be continued sufficiently long, *irritation* is excited. The latter effect ensues immediately if alcohol is brought into contact with a mucous membrane. Its strong attraction for water seems to be the chief cause of this action.

Alcohol is a powerful *antiseptic*, probably from the fact that it is capable, even when diluted, of preventing the development of septic germs, such as vibrios and bacteria, as well as of paralysing the activity of those already formed.

There is scarcely any other therapeutic agent the *internal action* of which varies so much according to the dose given. In *small quantity*, and slightly diluted with water, alcohol promotes the functional activity of the stomach, the heart, and the brain, while a like quantity, largely diluted, exerts but a limited influence upon these organs : if, however, the dose of alcohol be often repeated, it is readily assimilated, and, becoming diffused throughout the system, undergoes combustion within the tissues of the body, imparts warmth to them, and yields vital force for the performance of their various functions. Simultaneously with this consumption of alcohol the body of the consumer is often observed to gain in fat, a circumstance due to simple accumulation, the fat furnished by the food remaining unburned in the tissues, because the more combustible alcohol furnishes the warmth required, leaving no necessity for the fat to be used for that

purpose. A quantity of 100 cubic centimetres of alcohol *per diem* (about three and a half fluid ounces) —equivalent to about one litre of Rhine wine of medium strength—is sufficient to supply between one third and one quarter of the whole amount of warmth requisite for the human body during the twenty-four hours. The warmth so supplied cannot be measured by a thermometer, however, any more than can that furnished by the internal combustion of other hydrocarbons, such as the oils and sugars. The subjective impression of increased warmth usually experienced after taking a dose of any alcoholic liquid is deceptive, and is only due to an irritation of the nerves of the stomach, and to the increased circulation of blood through the cutaneous vessels, particularly those of the head.

The increase of the action of the heart after taking alcohol is well known, and has often been expressed in figures. Former experiments had also established this fact with regard to the respiration. The quantity of the inhaled and exhaled air in healthy men was increased by 7 to 9 per cent. ; in one instance, after taking champagne, by 15 per cent. The more recent experiments of Binz and Wendelstadt have furnished the following results :

1. Moderate quantities of alcohol produced in healthy persons a rise of 60 to 100 per cent. in the amount of air respired when the subjects were tired by hard bodily work.

2. A rise of a lower percentage was present when the persons were asleep under the combined influence of work and of alcohol. This proves that the vital force of the respiratory nerves and muscles may be increased by the alcohol even when the psychical centres are transiently paralysed by it.

3. An unfavourable reaction, such as the occurrence of a period of unusual diminution of respiration following the period of increased activity, has never been observed.

4. The stimulating function of alcohol on the tired respiration showed itself best when alcohol was given in the form of a thoroughly natural fine-flavoured wine.

Doses somewhat larger, but still sufficiently moderate not to cause intoxication, act, for the most part, in the same way ; but, as an additional effect, they produce a distinct decrease in the temperature of the body, lasting half an hour or more. As far as the matter has hitherto been explained, this latter effect depends upon a directly depressing influence exerted by alcohol upon the working cells of the body, and upon a temporary paralysis of the vaso-motor nerves. The latter is followed by dilatation of the superficial vessels, particularly those of the head, in consequence of which a larger surface of blood is exposed, and the loss of heat by radiation into the air is increased, the temperature of the circulating fluid being thus lowered ; while, the combustion carried on by the cells being retarded, the generation of heat from this source is diminished. The quantity of carbon dioxide eliminated is thus diminished, as is also the amount of urea excreted. After the organism has become inured to the action of alcohol, these effects upon the temperature of the body are less distinctly marked, and may be entirely absent.

The agreeable excitement at first caused by such doses of alcohol is succeeded by a reaction, characterised by lassitude and drowsiness, the latter condition usually lasting longer than the previous one of exhilaration.

The symptoms of intoxication produced by *large doses* of alcohol are sufficiently well known. When the abnormal condition of excitement in the brain induced by this stimulant has been kept up, almost without intermission, for a length of time, or when it is suddenly withdrawn after the organ has been long subjected to it, the disturbance brought about is so great and persistent as to result in a complete overthrow of the reasoning faculties, and the condition known as *delirium tremens* ensues. At the same time that this pernicious influence is being exerted upon the cells of the brain, fatty accumulation may take place in other organs, particularly in the liver, heart, and connective tissues; the blood-vessels become diseased, and, in many instances, cirrhosis of the liver, kidneys, and meninges makes its appearance, as part of the general disorder of nutrition. The shrinking of connective tissue, characteristic of this last-mentioned complication, seems to depend upon the direct irritation caused by the presence of unoxidised alcohol.

Under ordinary circumstances, and after the consumption of moderate quantities of alcohol, only slight traces of it are to be detected in the urine, in the breath, and in the perspiration; none is present in the milk. A long series of experiments made by the writer's assistants, Dr. Bodlaender and Dr. Klingemann, on healthy men and animals proved that altogether, at the most, 5 per cent. reappears. The feces do not contain any alcohol at all. These experiments have been repeated by Dr. Strassmann (Berlin), and confirmed in every essential point. As regards the breath, pure alcohol imparts no odour to the exhalations of the body; the ethers and fusel oil, on the other hand, do so by reason of their being less readily combustible. It is very probable that alcohol is completely oxidised into carbon dioxide and water during the process of assimilation; at least, no other secondary products resulting from its disintegration have as yet been detected.

THERAPEUTICAL APPLICATIONS.—There can be no doubt that a healthy organism, supplied with sufficient food, is capable of performing all its regular functions without requiring any specially combustible material for the generation of heat and the development of vital force. But the case assumes a different aspect in sickness: here, while the metamorphosis of tissue goes on with its usual activity, or with increased energy, as happens in many diseases, the stomach, refusing to accept or to digest ordinary food, fails to supply material to compensate for this waste. Under such conditions, a material which can be most readily assimilated by the system, and which, by its superior combustibility, spares the sacrifice of animal tissue, is especially called for; and such a material is found in alcohol. *Small but often repeated doses* of alcohol, largely diluted with water, are generally well tolerated by the weakest stomach; and, thus given, the absorption and oxidation of the spirit goes on without difficulty or effort on the part of the patient's system. The less patients have been previously accustomed to the use of alcohol, the more marked are the good effects derived from the drug in the event of illness.

According to the experiments of Dr. Frankland and others, the burning of 1.0 gramme of alcohol yields sufficient heat to raise the temperature of seven litres of water 1° C.; and the burning of 1.9 gramme of oil suffices for nine litres. Now,

in taking three tablespoonfuls of oil daily, we yield about the same amount of warmth to the body as is given by four tablespoonfuls of absolute alcohol—the quantity contained in a bottle of light claret or hock. The oil, however is digested and oxidised by the organs of the body with difficulty, while, for the assimilation of the alcohol, scarcely any exertion of the working cells is required. Thus, it follows that heat-producing material, sufficient to supply nearly one-third of the whole amount of warmth required by the body within twenty-four hours, is offered in a quantity of 100 grammes (about three and a half fluid ounces) of alcohol. In this sense alcohol is a *food*; for we must regard as food not only the building material, but all substances which, by their combustion in its tissues, afford warmth to the animal organism, and, by so doing, contribute towards the production of vital force, and keep up the powers of endurance. Alcohol, therefore, diluted with at least 90 per cent. of water (in any convenient form of beverage), may be given with advantage, in small but oft-repeated doses, in most of the acute and chronic diseases where the digestive organs, from any cause, refuse to tolerate a more substantial form of nourishment, at least in quantities that would answer the necessities of the case. In such cases it is certainly not sufficient to call alcohol merely a *stimulant*. If alcohol served here only in the quality of a stimulant, its effect would soon pass away, leaving the patient more exhausted than ever; for the human organism is so constituted that it cannot be driven to perform its functions by the application of measures that simply stimulate, without supplying some new force to take the place of that put forth by the organs of the body under the impulse of excitement. To take a familiar illustration, alcohol thus given stimulates no more than does the readily combustible coal which we put in small quantities upon a languid fire, to prevent its going entirely out.

Experiments in the writer's laboratory (Geppert) have contributed the following facts to this part of the question. 20 to 75 cubic centimetres of absolute alcohol, taken in water or in the form of port, brandy, or sparkling hock by healthy adults, who were accustomed to take no alcohol or only a moderate quantity, hardly altered the quantity of the consumed oxygen, and likewise left unaltered or very slightly decreased the excretion of the carbonic acid.

The principal point in this result is the unchanged standard of the consumption of oxygen. We know that the consumed alcohol is burnt in the organism, a minute quantity excepted. The alcohol was thus unable to increase oxidation, as its adversaries have still continued to assert; it had not contributed to a more rapid wasting of the organism; nor had it made the regular equal march of this wasting irregular and slow. On the contrary, it had substituted itself simply as fuel in order to sustain the normal temperature of life, the existence of which is necessary to keep the whole machine in motion. Alcohol acts here, generally speaking, as if we had given the person experimented upon oil or sugar. A part of the disposable oxygen which would serve for oxidising other substances serves for the combustion of the alcohol, and keeps them intact for the organism.

Medium doses of alcohol act powerfully upon the brain and heart and are therefore serviceable as

real stimulants in cases where it is desirable to excite the cerebral and circulatory systems to greater activity. We must not forget, however, that while exciting this increased activity, such doses do not elevate the temperature of the body; on the contrary, where the effect can be measured, it is found that they depress it a little. By continuing to exhibit such doses, we can sometimes (in erysipelas, puerperal peritonitis, and similar diseases) lower febrile heat by alcohol where even quinine proves ineffectual. The consequences of this decline of fever-heat are an immediate restoration to consciousness, if delirium or stupor has been present; and, in any case, a general improvement in the feelings of the patient. Todd and his school, before the application of the thermometer, called this *the effect of stimulus*, while in reality the improvement is, to a great extent, due to the diminution of febrile disturbance. As fever-patients can tolerate large quantities of alcohol without showing any sign of intoxication, it is allowable, and sometimes even necessary, to increase the scale of doses beyond the limits ordinarily prescribed.

Alcohol has been given during the night to hectic phthisical patients as a preventive against copious and exhausting attacks of sweating, and with a gratifying amount of success. Such patients certainly tolerate the remedy much better than has hitherto been generally supposed. It need hardly be said that, in cases of cardiac excitement, not resulting from fever, alcohol is to be used with great caution.

MODE OF ADMINISTRATION.—One of the most important, but at the same time most difficult, points for decision is the exact nature and quality of the alcoholic drink to be prescribed or allowed to a patient who may require alcohol in some form. For *general use*, a pure claret, hock, or Moselle wine is the form of alcohol most to be recommended. Cognac, champagne, old gin or whisky, and the heavier Southern wines, may also be used according to circumstances. But whatever drink may be selected, it must at least be free from fusel oil to such an extent that a healthy man, even after imbibing a considerable quantity, will not feel any other effects than those of a pure stimulus; that is to say, an agreeable exhilaration of spirits, neither accompanied by a sense of weight in the head, nor followed by that persistent overfilling of the cerebral vessels and dulness of ideas characteristic of the physiological effects of fusel oil.

The *fusel oils* (so called from their oily qualities) consist chiefly of propyl, butyl, and amyl alcohols, of which the last-named forms the largest proportion. In order to examine any specimen of alcohol with reference to its purity from these objectionable constituents, it is only necessary to rub a few drops between the palms of the hands for half a minute, by which rapid evaporation is caused, and then to smell the moist spot left on either palm. If the alcohol be pure, no odour whatever should remain, as ethyl alcohol evaporates very quickly; amyl alcohol, on the contrary, is much less volatile, and, if present in the liquid, will not have evaporated, so that its peculiar and unmistakable odour will remain to attest its presence as an impurity in the specimen examined.

This test is not applicable to the more complicated liqueurs and wines, as these all contain certain odoriferous organic principles of their own, which might disguise the smell of the fusel oil. The

inoffensive quality of any given preparation, as a wine or spirit, can only be relied upon when one knows by experience that it *is* pure; and then it should always be obtained, if possible, from the same source, so as to ensure uniform purity.

To facilitate the process of estimating the quantity of any particular beverage necessary to be administered in order to produce a given effect, a table is subjoined showing the percentage of absolute alcohol contained in average specimens of the different kinds of wine, beer, &c., in common use.

Absolute Alcohol contained in—

Kumis (a fermented liquor made from milk or whey), from 1 to 3 vol. per cent. Kefir is the same, but derived from the milk or whey of the cow, while kumis comes from the milk or whey of the mare. Both contain much carbonic acid, which renders them easily digestible.

German Beer: from 3 to 5 vol. per cent.

English Beer: from 4 to 7 vol. per cent.

Hock or claret: from 8 to 11 vol. per cent.

Champagne: from 10 to 13 vol. per cent.

Southern wines (port, sherry, madeira, &c.): from 14 to 17 vol. per cent.

Brandy and strong liqueurs: from 30 to 50 vol. per cent.

For *antipyretic purposes* one will need to give an adult daily not less than the equivalent of fifty cubic centimetres (about two fluid ounces) of absolute alcohol, in divided doses within an hour or two. Taking this as a starting-point, the dose suitable for each individual case can be estimated accordingly.

The great quantity of carbon dioxide contained in certain 'sparkling' wines acts upon the temperature of a fever patient much in the same favourable manner as the alcohol itself; and when alcohol is to be taken as a food, it would seem that the impregnation with carbon dioxide facilitates its absorption.

All that has been stated thus far with regard to the use of alcohol in sickness applies to children as well as to adults. Of course no reasonable person would accustom healthy children to the use of alcoholic beverages; but, in cases of disease, really good and pure wine or brandy can be advantageously employed, even for infants, either as a *stimulant*, an *antipyretic*, or an *article of food*, according to circumstances.

In conclusion the conviction must be expressed that a healthy and well-nourished individual has not the slightest necessity for alcohol at any time or in any form, and that the practice of drinking strong alcoholic liquors cannot be too strongly condemned.

Physicians prescribing alcohol should take every care as to the conditions under which it is administered, lest the patient, while recovering from one disease, should contract another, scarcely less disastrous—a continuous craving for stimulants. The good effects of alcohol are most prominent in patients who have not been accustomed to it while in health. See ALCOHOLISM.

For *external use* as an antiseptic and disinfectant, alcohol has been superseded by various more modern agents, of which carbolic acid, iodoform, and perchloride of mercury may be mentioned as the most important. Recently, however, its external use has been revived to a large extent, for cleaning instruments and fingers before performing surgical operations and for the application of lasting bandages (*Dauerverband*) in cases of acute infectious skin-diseases, such as erysipelas and phlegmon. The results are highly praised. At all events, alcohol is the least obnoxious of all chemical disinfectants.

C. BINZ (Bonn).

ALCOHOLIC INSANITY.—See ALCOHOLISM.

ALCOHOLISM. — **DEFINITION.** — **GENERAL FACTS AND PRINCIPLES.** — Alcoholism is a term now generally used to denote all the morbid effects of the excessive use of alcohol, not only on the brain and nervous centres, but also on the other bodily organs and functions and on the mental faculties. In this article the nervous and mental effects will be chiefly referred to, as the pathological changes in the other organs will be found described among the diseases to which each organ is subject.

The physician cannot rightly approach the subject of alcoholism except by keeping in mind that the strongest affinities and the first effects of alcohol are always manifested in relation to the nervous system; that the most marked of these effects are observed on the brain-cortex in its highest functions and most delicate co-ordinations; that its injurious results on the peripheral organs—looking on the brain-cortex as the centre of the organism—are largely due to its stimulating and irritating effects on the cortical centres, where the various organs and functions are represented and from which impulses are transmitted peripherally. Almost equally important is the fact that every function of brain and nerve becomes affected in every case of alcoholism, though in different cases mental, motor, sensory, vaso-motor, trophic, and sympathetic neuroses may differ enormously, the disturbances in one function being so great, and in the others so slight, as to make it appear as if one function only were affected. The explanation of the fact that in different individuals alcoholism varies so greatly in its effects seems to be found in (1) the hereditary and innate nervous constitution and qualities of the person affected; (2) the general habits and occupations of the patients, their ages, social surroundings, and general environment; and (3) the kind of drink taken and the way it is imbibed—e.g. whether taken with food or not, whether taken in bouts or by steady soaking. The nervous, unstable youth, whose mother was insane, may have a sharp attack of mania; the professional head-worker may have an ordinary attack of delirium tremens; the town artisan may have convulsions, and the farmer and outdoor sportsman may show no appreciable effects whatever, although each of the four has drunk the same amount of alcoholic liquor. Steady over-drinking may in one man cause tremors of the limbs, in another peripheral neuritis, in another sensory disturbances, in another spinal paralysis, in another hallucinations, in another delusions and insane impulses; or some of these symptoms may exist, and commonly indeed do exist, in combination. In one man there may be elevated temperature, in another profuse perspiration, in another weakened action of the heart and lowered vascular tone, in another arterial and capillary degeneration, in another hepatic disturbance, in another renal disease, and in another an abnormal deposit of fat—all as the results of alcoholic excess.

A partial 'tolerance' of alcohol may be established in certain individuals, and there are strong grounds for believing in Archdall Reid's theory that an alcoholic 'immunity' is established in a race or community through many successive generations having drunk hard, the weakest and the most susceptible to the influence of the drug being gradually eliminated and the fittest only surviving. There are unquestionably racial differences of a marked kind in regard to the effects of alcohol. Most savage and primitive peoples, however strong

and well-developed physically, succumb to its morbid influences very soon and very completely, many of them suffering speedy extinction whenever they take to it. Yet, on the other hand, some of the advancing and dominating modern races—notably the Scandinavians, English, and Germans—have been great consumers of alcohol, excess being frequent in them all. Whether or not it is owing to the fact that alcohol is more consumed by urban than by rural populations, it is at all events certain that alcoholism is proportionally far more common in our modern cities than in the rural districts.

Another most important general principle to be kept in mind is that alcohol brings out, complicates, and aggravates the effects of every other disease. Every physician in extensive practice knows this well, and always takes it into account in his prognosis and treatment. No fact is better recognised by the medical student of vital statistics than that a high disease-rate and a high mortality-rate invariably accompany an excess in the use of alcohol in every form in any population. The universal human craving for, and use of, some nerve-stimulant or sedative, apart from food, is also an ultimate physiological and psychological fact that has to be boldly faced by the philosophic student of the effects of alcohol. Haschisch, tea, tobacco, coca, opium, and alcohol, have a common fascination for the human brain. The same brain which craves for alcohol and tends to exceed in its use is also that which is liable to a craving for morphine, chloral hydrate, cocaine, and all such stimulant-sedatives. The effects on the nervous system of excess in the use of all these have certain common characters with those produced by alcoholism. Certain of the toxins of the infective diseases such as syphilis and diphtheria, and some of the mineral poisons, such as mercury, lead, and arsenic, have also some effects resembling those of alcohol, both on the peripheral nerves and on the nerve-centres.

Another general principle to be kept in mind is that commonly alcohol attacks the *weakest point* of the organism, and attacks it at its *weakest time*—whether the weakness be due to heredity, critical periods, over-exertion, injury, or disease. A man may have stood a moderate amount of alcohol well and had no uncontrollable craving for it till he had a severe attack of influenza; yet after that he may become a drunkard and rapidly develop alcoholism. The same thing may happen to another man after his energies and tissues have been exhausted or stimulated by stress of business, or have begun to weaken through senile changes. In the case of women it is common enough to have morbid alcoholic cravings with consequent alcoholism developed at menstruation, during pregnancy or nursing, or at the climacteric period. The same thing may occur after injury to the head through railway accidents and other traumatism. It is a consideration well worth more careful study than it has yet received, whether some of the symptoms of alcoholism may result not only from the direct toxic effects of the stimulant on the nerve-elements and other tissues, but also through secondary toxins produced or let loose by the interference with normal metabolism which the drug doubtless causes. The writer thinks it certain that the syphilitic poison may be dormant till an excess of alcohol wakes it into destructive activity. Some of the alcoholic scleroses and cirrhotic conditions, both in the nervous centres and in other organs, may perhaps be accounted for in this way.

All these considerations enable us to understand in some degree the enormous range and variety of the pathological phenomena met with in alcoholism, and to realise its contributory effects in producing a part of the human degeneracy which we see in our modern large cities and manufacturing districts.

FORMS OF ALCOHOLISM :—

1. *Mania a Potu* or *Delirium Ebriosum* is that transitory insanity or delirium which is seen in the case of persons—usually young—with unstable brains from a bad heredity. To produce this in such persons very little drink is needed. A few glasses of spirits may in such cases set up a wild unmanageable fury and leave as little sane consciousness as we see in epileptic acute mania, which in some ways it resembles. Sleeplessness, mental and muscular excitement, violence, sometimes homicidal and suicidal tendencies, often a slightly raised temperature and a wild distracted facial expression are the chief symptoms. The onset is very sudden. The liquor admittedly acts on such a brain as a violent toxin to the cortex, disturbing the output of energy, destroying for the time inhibition, and causing mental explosiveness. The drunkenness often runs into the mania, and the one therefore is sometimes confused with the other. There are none of the hallucinations, tremors, high fever, or exhaustion characteristic of the true *delirium tremens*. The excitement only lasts for a few hours or a day or two at the most, and then passes off completely, leaving a little mental confusion. The proper treatment is a large dose of chloral hydrate and bromide of potassium, or of sulphonal, with as much liquid food as possible. The patient must be carefully watched.

2. *Delirium Tremens* or *Acute Alcoholism* is the next form of alcoholism in the ascending scale of seriousness and duration. From the psychiatric point of view this is a typical 'excited melancholia' with intense depression, hallucinations of sight, fleeting delusions, often suicidal impulses, incoherence of speech, failure of attention and memory, and a tendency to mistake the identities of persons about the patient. In addition, there are motor restlessness, muscular inco-ordination and tremulousness, constant purposeless movements, complete loss of the appetite for food, often sickness, foul loaded tremulous tongue, a rapid loss of body weight, a haggard expression of face, a very weak pulse, and a temperature of from 99° F. to 104° F. The patients are often suicidal or homicidal. The writer believes that a vast number of the sensational suicides reported in the newspapers, which are preceded by the murder of wife and children, take place when men are passing into acute alcoholism. If there is a taint of insanity in the blood the mental symptoms are apt to be more accentuated, and persons of a specially neurotic constitution are more liable to the disease than persons of more stable cerebral constitution. The whole condition is one of great weakness and real brain-exhaustion; in some cases there is even danger to life. It is a pronounced cerebral toxæmia. Sometimes the ordinary motor reflexes are exaggerated; at others, especially if many previous attacks have occurred, they are diminished. The proper treatment consists in careful nursing and watching night and day by a sufficient number of skilful trained nurses or attendants; and in frequent feeding with beef-tea, milk and potash-water, and soups. Rest in bed is advisable at first, but very soon the

patient should be taken into the fresh air and allowed moderate exercise. Hypnotics and sedatives may be given judiciously and with liquid foods. Paraldehyde is a very safe drug, but needs to be given in large doses (two to five drachms), and each dose may be aided by half a drachm of bromide of potassium. Chloral hydrate with bromide of potassium and sulphonal are also useful. If the patient cannot be induced to swallow these, paraldehyde may be given by the rectum, or hyoscine injected hypodermically ($\frac{1}{160}$ grain, or at most $\frac{1}{72}$ grain); morphine is not to be recommended for general use, but it is valuable in a few special cases. The patients usually recover in from three days to three weeks. Some of them die suddenly of exhaustion, especially if there has been pre-existing renal, cardiac, or cerebral disease. If many attacks have preceded the one under treatment, hallucinations of hearing are apt to follow, complicating the visual hallucinations and persisting long after they have disappeared. Such patients may 'hear voices' for months after an attack, and this condition may develop into delusional insanity. In the case of the well-to-do, trained attendants are needed; in that of the poor, a hospital or an asylum is the only means through which supervision, safety, and proper treatment can be obtained. Mechanical restraint of the patient is to be avoided if possible.

3. *Chronic Alcoholism* is a term covering a large extent of pathological territory, and its multiform symptoms in different cases are not easy to enumerate and describe in a small space. Every mental faculty may be affected, so that the patient is technically insane; or so little diminution of mental energy or such limited affection of mind may be present that the patient may not legally be of 'unsound mind.' Every other brain-function as well as mind—voluntary motion, special and general sensation, nutrition, digestion, excretion, and the metabolism of every tissue and organ may all suffer. The cause of the disease is always a steady persistent drinking for months and years, so that the toxæmia is general and the tissue-changes widely diffused. Such changes are apt to be of a structural kind, especially after repeated attacks and steady drinking. The sufferer from Chronic Alcoholism is in fact always an 'habitual' drunkard and not one who merely indulges in bouts and sprees. The first symptoms of the condition are always mental and moral. The patients become mentally obtuse, inaccurate, lazy, changed in their sense of duty and in their affection towards relations and dependents. They do not feel 'up to the mark,' but conceal this fact or assign every cause for it but the true one, which they hide and vigorously deny. They are irritable, forgetful, and frequently suspicious to a morbid degree. They become generally untrustworthy in conduct, in business, and in friendship. The face and eye—those 'mirrors of the soul'—undergo a deterioration and lowering in expression, the one being red and sodden and the other bleary. The sleep is bad and unrefreshing, and the bottle is perpetually resorted to more and more in the vain hope of securing sound sleep, with the result that all the symptoms are increased next morning. The muscles begin to show a tremor, so that the patient cannot write well, cannot hold things steadily or perform satisfactorily delicate muscular co-ordinations. The speech is often tremulous and suggestive of early General Paralysis of the Insane. The ordinary

motor reflexes, particularly the knee-jerks, are commonly found to be dulled or even lost; but there are exceptions to this rule. There may be signs of incipient Spinal Alcoholic Paralysis, to be fully developed later on. The tongue is commonly furred, flabby, and tremulous; there is no appetite; and there may be sickness from chronic gastric catarrh. The early symptoms of *peripheral neuritis*, especially in the female cases, may then be appearing. These neuritic symptoms commonly consist of tenderness of the limbs on pressure or in walking, with wasting and weakness of the extensor muscles leading to foot-drop and wrist-drop. There may be discomfort, pains, or tingling in almost any part of the body, through the toxic influence of the spirit on the sensory centres or afferent nerves in different cases. The muscles are at first flabby to the touch: as the disease becomes fully developed there is rapid loss of flesh. There may be alcoholic convulsions in the early stage, just as in acute alcoholism. Insomnia is a marked symptom and tends to increase still further the nervous exhaustion and mental disturbances. The patient's mental state gets worse and resembles that of an insane person. The temper becomes so bad and so uncertain that 'nobody can live with' the patient; or he gets really dangerous and commits assaults on members of his family or on his nurses. Hallucinations of hearing come on, and the voices or sounds or noises believed to be heard are always disagreeable or irritating. The writer has known several cases of homicide, and many of suicide, attempted or committed at this stage; indeed it is well for this danger to be constantly kept in mind in treatment. Suspicions and suspicious delusions about those near them, especially about those who are trying to stop the supplies of liquor, are very common. The patients say they are being poisoned or starved or cheated or cruelly treated. They think men are in the house to rob and murder them, and they sometimes buy and keep in their rooms weapons with which to defend themselves against their imaginary enemies and persecutors. Some of the cases are impulsive and mentally epileptiform in character. Such patients may suddenly and without warning break windows and furniture, upset tables covered with dishes, jump into water, and assault without any provocation those near them. The power of attention and concentration of mind is markedly paralysed. The affective nature is commonly much changed. The natural and previously existing love and affection for relatives and friends changes to indifference or to actual dislike. The memory, especially for recent events, becomes very bad. The ethical condition of the patient steadily deteriorates, so that there are seen senseless lying, cruelty, degeneration of personal habits, and loss of the social instincts. In fact, the higher intellectual, emotional, and moral faculties undergo a steady degradation tending towards their suspension. Some authorities divide the mental change into two periods, the one here described being the first, and the second being one of dementia, in which the memory especially almost disappears. The motor condition of this second stage is that of paresis or paralysis; this in time extends even to the sphincters. The first stage is typically one of tremor, hallucination, irritability, and moral perversion, the second that of paresis and mental extinction.

PATHOLOGY.—The pathological changes accompanying the first stage are those of cortical conges-

tion, thickening of the pia-arachnoid, and enormous proliferation of the neuroglia-elements of the cortex. The coats of the cerebral arterioles and capillaries are thickened and fatty, and atheromatous changes occur; heaped masses of proliferated nuclei appear on the external coat which almost block up the lymphatic perivascular space. The neuroglia forms a dense 'felted' layer extending from the pia mater through one fourth of the thickness of the cortex. In many cases the pia mater adheres to the outer layer of the cortex in places, and the lining membranes of the ventricles become granular. The cells undergo all kinds and degrees of pigmentary and granular degeneration. The second stage corresponds pathologically to the general atrophy of the brain with especial wasting of the convolutions, and the deposit of masses of amyloid bodies between the pia mater and cortex as well as throughout the brain substance. The brain-cells have meanwhile largely undergone the process of atrophy. Bevan Lewis directs special attention to the fact that the motor-cells of the fifth layer exhibit fatty change, and together with the layer of spindle-cells below them undergo extensive degeneration and absorption. Fatty embolisms and minute aneurysmal dilatations are also commonly found in the small vessels of the white substance of the brain. Thus it is seen that modern methods of microscopical examination of the brain exhibit sufficient pathological changes in the membranes, neuroglia, vascular and lymphatic structures, and cells to account fully for the mental and motor defects of the Chronic Alcoholic. His brain under the microscope after death is as pathologically distinctive and as far from its average normal state as is the man himself in mind and body while alive. See *INSANITY*, Pathology of.

DIAGNOSIS.—The chief conditions that are liable to be mistaken for Chronic Alcoholism are General Paralysis of the Insane in its early stages; certain syphilitic vascular and gummatous affections of the brain-cortex; certain kinds of cerebral softening and apoplectic states, especially those attacking cortical areas; the effects of sun-stroke in certain cases; and post-epileptic states. The clinical resemblance between certain early General Paralytics and certain Chronic Alcoholics is so close that it may be necessary to wait for a time before a definite diagnosis is made. The history of continuous drinking is of course the most relevant fact in determining the disease as distinguished from the other states just mentioned. But General Paralytics and people with sunstroke and brain-softening often enough drink hard, and there may thus be produced a confusing combination of Alcoholic and other symptoms.

PROGNOSIS.—The prospects of the Chronic Alcoholic are on the whole bad; but a certain number of cases do recover and are able to resume their business and places in society. Recovery is never a speedy process. A certain number are half cured, and live for long periods, leading a sort of sub-life with damaged minds and brains. But the majority go on from bad to worse, and die in a few years from the advancing destruction of nerve-elements, or from disease of the heart, liver, or kidney.

TREATMENT.—The treatment of such cases begins by an insistence on a *total* abstinence from alcoholic drinks as the most essential condition of cure. The use of tonics, nerve-stimulants such as the mineral acids and strychnine, and liberal doses of

iodide of potassium are at first indicated. Sometimes the continuous galvanic current may be employed. Simple diet combined with a regulated physiological life spent largely in the fresh air, with work and with a good moral atmosphere, comprises the chief means of treatment. Control from without in some shape is essential in most cases. If the patient is technically insane and can be certified and sent to an asylum, this course affords in most cases the best chance of cure, at least until a proper law for the treatment of inebriates is passed by the Legislature.

Alcoholic Dementia and Degeneration.—There can be no doubt that a man may induce some of the most marked and far-reaching pathological effects of alcoholic excess without having once been 'drunk'—without ever having had acute or chronic alcoholism or mental disturbance in any active form. He may ultimately reach almost complete intellectual dissolution, utter moral and affective perversity, and total loss of memory through the steady brain-poisoning of a respectable and almost unobserved excess. He takes nips of whisky morning, noon, and night, so that his brain-cells are never free from its influence, but he never reaches intoxication. The result is that at forty he becomes inaccurate and makes mistakes in business; at forty-five he is unstable and stupid; at fifty or sixty his memory is gone, he is unfit to do any business whatever, his muscles are flabby, his brain is undergoing atrophy, and he is an 'old man,' well on in his alcoholic dotage. This is a real dementia of a special kind where the memory is specially affected, there often being a stage of irritability and confusion before it disappears. Dr. George R. Wilson points out that retention of the impression, reproduction of the image, and recognition are all affected alike in intoxication and in alcoholism. Often, too, a stage of silly, easily imposed on optimism precedes the more complete dissolution of dementia. Alcoholic dementia in some degree may and does usually follow uncured Chronic Alcoholism if the patient has a strong enough constitution not to have been killed off by that disease.

5. *Dipsomania* is a condition which is connected with and may lead to Alcoholism, but is essentially different in itself, being in reality a psychological defect or disease with no necessary bodily symptoms. See DIPSOMANIA.

6. *Alcoholic Neuritis.*—See NEURITIS, MULTIPLE.

7. *Alcoholic Spinal Paralysis.*—In addition to the paresis and paralysis from neuritis, certain cases suffer from complete or partial paralysis from chronic degeneration of the spinal cord. Such cases are incurable.

RELATION OF ALCOHOLISM TO SUICIDE.—There is a close relationship between alcoholism and suicide. A very considerable proportion of the suicides of the country take place in the early stages of, and as the result of, attacks of this disease. Those tragedies especially where a father first kills his wife and children and then himself are due to this disease. Dr. W. C. Sullivan has lately shown by exhaustive statistics and observations that alcoholism and suicide have a close and special relationship, and that alcoholic suicide and suicidal attempts are apt to be of a special type, being 'more impulsive and more directly and immediately related to organic conditions in the individual.' The great practical

consideration to the medical practitioner is that the possibility of suicide should be thought of in every case of alcoholism which he has to treat, and should be specially guarded against where it exists. Homicidal attempts, alone or combined with suicide, are more commonly met with in chronic than in acute alcoholism.

HEREDITY AND PREDISPOSITION.—No exhaustive statistics exist which show the relationship of alcoholic excess to previously existing excess in ancestors or collaterals, or the precise danger of its transmission to descendants; nor has it been ascertained precisely what period of life is most liable to be affected by it, or what are the causes which most predispose to it, other than a general nervous instability and the regular and excessive use of intoxicants. There is an almost universal consensus of opinion on the part of medical men who see most of it that there is a very close connection between alcoholic excess and a certain quality of brain which is characterised by instability or explosiveness, or 'nervousness,' or depression, or a general weakness of inhibition, or by a tendency to periodic mental disturbance. Whether any acquired peculiarity can be transmitted or not, all medical experience goes to show that in many families successive generations of men and women are drunkards; that in most of the members of such families a tendency to excessive drinking will 'break out' in sudden extraordinary ways, sometimes at very early periods of life; and that in other members of such families insanity, epilepsy, developmental defects, and the neuroses generally are encountered with undue frequency. In some of the most marked of such 'hereditary' cases the craving for alcohol is manifestly a diseased craving, being uncontrollable by any effort of will on the part of the patient. In such families, too, there are certain crises and periods of life that are dangerous in this connection to many of its members, notably adolescence, pregnancy, childbearing, menstruation, and the climacteric. Some of the members of such families exhibit signs of intoxication after taking very small quantities of alcohol which would not so affect average people. In such families, too, the lowering effects of diseases, such as fevers and influenza, are especially liable to take the form of a craving for alcohol and a special intolerance to its effects. The members of such families, also, show special tendencies not only to alcohol, but to morphine, chloral hydrate, cocaine, and other nerve stimulants or sedatives. All the cases of alcoholism, however, do not come from such a neuropathic stock. A vast mass of the alcoholism of the country simply arises from excess which was led up to by moderate drinking; excessive use finally becomes habitual, gradually inducing a craving, and causing paralysed inhibition simply through its damaging effects on the brain-structure. Nearly all primitive and savage races become veritable dipsomaniacs when they have access to strong alcoholic drinks; and this is one of the chief causes of their disappearance in the face of advancing civilisation. They had no hereditary tendency to alcoholism, or to any of the neuroses of civilisation. This fact is really the strongest argument used by Dr. Archdall Reid as to acquired alcoholic insanity occurring in the nations that have had for thousands of years access to alcoholic beverages, so that now all such old nations—the Jews, Greeks, Italians, and French—are the most sober peoples. The great drinkers among them have gradually effected their

own destruction and elimination, and through the survival of the fittest the non-alcoholic cravers now survive.

T. S. CLOUSTON.

ALEPPO EVIL.—See ORIENTAL SORE.

ALEXANDERSBAD, in Bavaria.—Chalybeate waters and hydropathic establishment. See MINERAL WATERS.

ALEXIA (*a*, priv.; *λέξις*, word).—A term sometimes used in the nomenclature of aphasia to denote an inability to recognise written and printed characters.

ALGID (*algidus*, cold).—A word implying extreme coldness of the body, used only when it arises in connection with an internal morbid state, such as cholera, or a special form of malignant remittent fever.

ALGIERS.—Warm winter climate. Mean winter temperature 61° F., liable to rapid changes. Heavy rains not infrequent. See CLIMATE, Treatment of Disease by.

ALIMENT.—Food or aliment furnishes the elements required for the growth and maintenance of the organism; and, through its action with the other life-factor, air, forms the source of the power manifested.

The *alimentary products* as supplied by nature are resolvable by analysis into a variety of definite chemical compounds. These constitute the *alimentary principles*. Some are common to both animal and vegetable food, as, for instance, albumen, casein, fats, &c.; others are peculiar to either the animal or vegetable kingdom. Starch, for example, is met with only in vegetable, and gelatine only in animal products.

With reference to the alimentary principles, it must be understood that in no case do they exist in natural products in an isolated form, and no single alimentary principle is capable of supporting life. Although, however, it is with the alimentary products as a whole that we are practically concerned, yet, regarded from a scientific point of view, a knowledge of their constituent principles is required, to enable us to assign to them their proper value as alimentary articles; and for the purpose of systematic consideration some kind of classification is needed.

CLASSIFICATION.—The following grouping of the alimentary principles, based on chemistry, furnishes a classification which involves no theoretical proposition, and is practically convenient:—

Food is primarily divisible into *inorganic* and *organic* principles.

The *inorganic* principles consist of water, and the various saline matters required by the system. They are as much needed for the support of life as the organic portion of food.

The *organic* principles are subdivisible into *nitrogenous* and *non-nitrogenous*; and the *non-nitrogenous* are again further subdivisible into *fats* and *carbohydrates*.

The *nitrogenous* principles contribute to the growth and nutrition of the various bodily tissues, and furnish the active constituents of the secretions. They also undergo resolution in the system into urea, which is excreted, and a complementary portion, which is susceptible of application to force-production. They are thus capable of administering

to all the purposes fulfilled by the organic portion of an aliment.

The *fats* are applied to the production of heat and other forms of force. They seem also to be essential to tissue-development generally, besides yielding the basis of the adipose tissue.

The *carbohydrates* (starch, sugar, gum, &c.) contribute to the formation of fat, and are also applied indirectly, if not directly, to force-production.

There are a few principles, such as alcohol, the vegetable acids, and pectin or vegetable jelly, which do not strictly fall within either of the preceding groups. Alcohol occupies a chemical position intermediate between the fats and carbohydrates (see ALCOHOL); while the others are more highly oxidised compounds than the carbohydrates.

All *alimentary products* in the form supplied by nature contain organic and inorganic principles, and the organic principles comprise more or less of the nitrogenous and non-nitrogenous divisions. The non-nitrogenous division, however, is not always represented, looked at broadly, by both fat and carbohydrate. Milk, which may be regarded, from the position it holds in nature, as furnishing a typical representative of an alimentary article, contains principles from each of the groups specified in the preceding classification. See DIET.

ALI WAL NORTH.—See SOUTH AFRICA.

ALKALINE TIDE.—See ACIDITY.

ALKALINITY.—The blood and the majority of the fluids derived from it possess an alkaline reaction to most organic indicators. This reaction is in all cases due, not to free alkali, but to bicarbonates and bi-basic phosphates of the alkalis, of which the sodium-salts are most abundant. As a result, the tissues which are fed by these fluids also have an alkaline reaction, but here there is a selective preference for potassium-salts, and as a result there is found in most tissues a preponderance of potassium bicarbonate and di-potassic phosphate instead of the corresponding sodium-salts. It may be here incidentally mentioned that the alkalinity of the tissues is decreased after death by the formation of organic acids, and, as a result, *post-mortem* testing often gives an acid reaction. The blood-corpuscles also contain organic substances of a basic nature which are set free on 'laking' and as a result the alkalinity of laked blood is almost double that of whipped blood.

The normal alkalinity of the blood, as estimated by titration against standard sodium hydrate after addition of excess of standard tartaric acid and using litmus as an indicator, is given as equivalent to 0.2 grm. of sodium hydrate per 100 grams of blood.

It is a common error to suppose that the alkalinity of the blood is permanently affected by the secretion of gastric juice on the one hand, or by the alkaline secretions of the mouth and intestine on the other, for the acid and alkali of these secretions never leave the body, but are either neutralised or reabsorbed. The formation of such fluids, therefore, merely causes a fluctuation in the alkalinity of the blood. This can only be permanently affected by those fluids which are removed from the body, viz., the urine and sweat. See ACIDITY.

Of these two the urine is the more important regulator of the reaction of the blood, the sweat playing only a subordinate part, except under pathological conditions.

The degree of alkalinity of the chief alkaline secretions, in terms of equivalent amounts of sodium carbonate (Na_2CO_3), are as follows: Saliva, 0.08 per cent.; pancreatic juice (temporary fistula), 0.3 to 0.5 per cent.; succus entericus, 0.4 to 0.5 per cent.; bile, 0.3 to 0.5 per cent.

The causation and variation of the reaction of the blood are discussed under ACIDITY.

BENJAMIN MOORE.

ALKALIS.—**DEFINITION.**—Inorganic substances, which turn syrup of violets green, and turmeric brown; and restore the blue colour to litmus which has been reddened by acids: they combine with acids to form salts; and their carbonates are soluble in water.

ENUMERATION.—The only substances which correspond with the above definition are—Potash, Soda, Lithia, and Ammonia. The alkaline earths—Lime, Magnesia, Baryta, and Strontia—and the alkaloïds have a similar action on vegetable blues and yellows; but the carbonates of the former group are almost insoluble in water; while the latter contain carbon, and are therefore classed with organic substances.

PROPERTIES.—Ammonia is distinguished from the other alkalis by its volatility. The non-volatile alkalis are readily recognised by their spectra, and by the colour they impart to the blowpipe-flame, potassium giving it a violet, sodium a yellow, and lithium a carmine colour. Potassium and sodium are present as constituents of the body in considerable quantities; ammonium exists to a smaller amount; and lithium probably in traces. Sodium is found chiefly in the blood, potassium in the muscles.

ACTION.—When applied to the skin, dilute alkalis and their carbonates act as rubefacients. Pure ammonia is a vesicant, and potash and soda have a caustic action. Both caustic potash and caustic soda absorb water from the tissues, and form a corrosive fluid, which destroys the parts around, as well as that to which the caustic has actually been applied. To prevent this effect they are sometimes mixed with lime, which absorbs the water. A mixture of potash and lime forms the 'Vienna paste.' When inhaled, ammonia causes irritation of the respiratory passages, and increased secretion of mucus. This irritation excites reflex contraction of the blood-vessels and consequent rise of blood-pressure. When swallowed in quantity, the caustic alkalis and their carbonates produce symptoms of irritant poisoning. In the case of ammonia these symptoms may be accompanied by those of inflammation of the air-passages, caused by the irritant vapour. The best antidote is dilute acid, such as vinegar. In small quantities and diluted, alkalis increase the secretion of gastric juice before meals. After absorption into the blood they render this fluid more alkaline; while potash appears especially to accelerate tissue-change, and is accordingly classed among the alteratives. When injected directly into the blood, potash acts specially on the muscles, which it paralyzes. Ammonia stimulates the motor centres in the brain and spinal cord, the respiratory centre in the medulla oblongata, and the accelerating nerves of

the heart. When injected into the veins it therefore causes convulsions like those of strychnine, and quickening of the respiration and pulse. Alkalis are chiefly excreted by the urine; and potash, soda, and lithia lessen its acidity or render it alkaline. Ammonia is partly excreted unchanged, but a portion passes out in the form of urea and uric acid; and it does not render the urine alkaline like the others. Potash and lithia act as diuretics; soda to a less extent; and ammonia least of all. The diuretic action does not depend on any change in the blood-pressure. Potash and ammonia are diaphoretic. Potash lessens the tenacity of mucus. *See* ALKALINITY.

USES.—Dilute solutions of potash and soda relieve itching in skin-diseases. Caustic potash or soda is used to destroy warts; to cauterise poisoned wounds; and to establish issues. Ammonia neutralises the formic acid which renders venomous the stings of bees, ants, and mosquitoes, and is therefore applied to relieve the pain which they cause. The intravenous injection of ammonia has been recommended as an antidote in snake-poisoning; but the value of the remedy is not established. Mixed with oil, so as to form a liniment, ammonia is used as a rubefacient in sore throats, bronchitis, rheumatic pains, and neuralgia. It is inhaled to relieve headache; as a restorative in syncope and shock, when it raises the blood-pressure; and to facilitate expectoration in chronic bronchitis. Alkalis administered after meals act as antacids, and relieve heartburn. When given before meals they increase the secretion of gastric juice, quicken digestion, and relieve weight at the epigastrium, pain between the shoulders, and flatulence. Bicarbonate of sodium is usually given for this purpose, but when the stomach is very irritable, liquor potassæ is preferred, as it is considered to have a sedative action on the mucous membrane. Alkalis appear to lessen the transformation of glycogen into sugar, and they are used on this account in diabetes mellitus. Liquor potassæ sometimes helps to reduce obesity. Alkalis are used in the treatment of scrofula, rheumatism, and gout; but in the last-mentioned disease lithia is considered the most valuable, while potash is preferred to soda, as the urate of lithium is most soluble, and the urate of sodium least so. The salts of certain organic acids, such as the acetates or citrates, may be employed as remote antacids to render the urine alkaline, as they undergo combustion, and are converted into carbonates in the blood. Alkalis are given to lessen the acidity of the urine in inflammation of the bladder or urethra, and potash is employed as a diuretic in dropsies. On account of its stimulating action on the heart and respiration, ammonia is administered in adynamic conditions and in chronic bronchitis.

T. LAUDER BRUNTON.

ALKALOIDS and other ACTIVE PRINCIPLES.—**DEFINITION.**—An alkaloid is a substance having a definite composition as regards the proportions of the chemical elements of which it is composed, and capable of combining, like an alkali, with acids to form salts. All alkaloids contain nitrogen, carbon, and hydrogen; and all, except conine, nicotine, sparteine, and some others, contain oxygen in addition.

Besides alkaloids there are other active principles found in plants, which have also a powerful influence on the animal economy, but do not possess the

chemical properties just stated. They are mostly neutral in reaction; they do not form salts with acids; and only a very few of them contain nitrogen.

CHEMICAL COMPOSITION AND RELATIONS.—These are briefly expressed in the above definition. Thus morphine, for example, one of the alkaloids of opium, has always the chemical composition represented by the formula $C_{17}H_{19}NO_3 \cdot H_2O$, and it may unite with acetic acid to form morphine acetate, just as potassium may unite with the same acid to produce potassium acetate. But the empirical formula $C_{17}H_{19}NO_3$ represents only the percentage composition of the substance in the simplest numbers, and does not express how the atoms of the different elements are related to each other. For, just as the ethylic alcohol, with the composition C_2H_5O , is believed by the chemist, from its behaviour towards other bodies, to contain a 'radicle,' or group of atoms, C_2H_5 , having certain chemical properties resembling those of a base, such as potassium, K; and just as this radicle, C_2H_5 , may replace one of the hydrogens of water, so as to form alcohol ($C_2H_5 + H_2O = \overset{H}{\underset{|}{C}}H_3O + H$); so chemists have good

reason for believing that alkaloids belong to the group known as *amines* or *amides*, which are really ammonia, NH_3 , in which one or more of the atoms of hydrogen are replaced by a radicle; in other words, they are ammonia bases, combining with HCl without elimination of H_2O . Most alkaloids are derivatives of pyridine.

It is obvious that two or more alkaloids may resemble each other in percentage composition and still be very different, both in their chemical *structure* and in their physiological action. Thus strychnine ($C_{21}H_{22}N_2O_2$), quinine ($C_{20}H_{21}N_3O_2$), and cinchonine ($C_{19}H_{21}N_2O$), differ only in a few atoms of carbon or of oxygen, more or less; but they have different physiological actions, showing that their chemical structure, which is not indicated in these formulæ, must also be different. The physiological action of an alkaloid may also be modified by combining it with another substance. Thus, as was pointed out by Crum-Brown and Fraser, compounds of strychnine with methyl, ethyl, and amyl, do not present the well-known physiological action of that substance, but one analogous to that of curarine.

ENUMERATION.—The alkaloids and other active principles most familiar to the physician are:—Morphine, Apomorphine, Codeine, Thebaine, Narcotine, Papaverine; Atropine, Hyoscyamine, Hyoscyne, Daturine; Nicotine; Conine; Physostigmine or Eserine; Strychnine, Brucine; Quinine, Cinchonine, Cinchonidine; Caffeine; Cocaine; Theobromine; Acetanilide; Phenazone (antipyrine); Aconitine; Veratrine; Digitalin; Curarine; Muscarine; Santonin; Emetine; Pilocarpine; Salicin; and Strophanthin. For the alkaloidal substances formed in dead bodies and in animal tissues, see PTOMA.

SOURCES.—The majority of alkaloids are formed by plants. The function which they subserve in the economy of the plant is not known. Some plants produce only one alkaloid, while in others two or more are formed. A few of the alkaloids have been produced synthetically by the chemist.

PHYSIOLOGICAL ACTION.—Alkaloids have various degrees of physiological activity when introduced into the animal body. Many are slow in their action, and a large dose is required to produce any observable effect; while others act more rapidly,

and are so potent that even a minute dose may destroy life. Compare, for example, narcotine, one of the alkaloids of opium, with nicotine, the alkaloid of tobacco. Twenty to thirty grains of the former have been taken by the human subject without producing any marked symptoms, while the twentieth part of a grain of the latter may induce symptoms so severe as to threaten life. It is also well known that alkaloids may have a different kind of action on different animals. Thus one-fourth of a grain of atropine will produce serious symptoms of a complex character in a dog, while three or even four grains may be given to a rabbit without causing any more marked effect than dilatation of the pupil. In considering the physiological actions of these substances, it may be borne in mind that some of them do not readily decompose and are excreted in whole or in part unchanged. Others split up quickly into simpler bodies and produce rapid but transient physiological effects; while others again which resist decomposition in the blood or tissues may produce no appreciable results for a time, but when they do begin to break up, the effects may be sudden and violent.

Alkaloids have frequently a double action on different parts of a great physiological system; and their action on a particular group of animals will depend on the relative degree of development of the parts of the system in that group. Thus most of the alkaloids of opium have such a double action—a convulsant action resembling that of strychnine, due to their influence on the spinal cord, and a narcotic or soporific action, due to their influence on sensory centres in the brain. Hence, in animals where the spinal system predominates, as in frogs, these alkaloids act most markedly as convulsants; while in the higher mammals their principal action is apparently on the encephalic centres, which have now become largely developed.

Passing to the consideration of the action of the individual substances, we cannot do more than give, by way of example, a brief *résumé* of our knowledge regarding a few of them.

1. **Morphine** ($C_{17}H_{19}NO_3$)—an alkaloid of Opium. In the frog this substance has a narcotic followed by a tetanic action. At first there is a state of depression of the brain and spinal cord, followed sooner or later by tetanic spasms or increased reflexes. Death occurs from exhaustion. Pigeons have been found to possess a remarkable power of withstanding the influence of this drug—an ordinary-sized bird requiring about two grains to kill it. Rabbits become partially somnolent, show a tendency to reflex spasms, and tolerate a large dose—say about one half to one grain per pound weight of the animal. In the dog the intravenous injection of even one tenth of a grain (for a small animal) causes agitation followed by sleep; the pulse and respiratory movements are slowed; the smaller arteries become dilated; the pupil is contracted; and, if the dose be large, death may be preceded by convulsions. In the higher mammals morphine acts chiefly on the sensory apparatus, both peripheral and central.

2. Other alkaloids of opium have also been investigated:—(a) **Narceine** ($C_{23}H_{29}NO_3$) has practically no action. Even in large doses it does not produce convulsions or sleep. (b) **Codeine** ($C_{18}H_{21}NO_3$) has an action mainly like that of morphine but much feebler. (c) **Thebaine** ($C_{19}H_{21}NO_3$) causes tetanic convulsions, thus

resembling strychnine. (d) **Narcotine** ($C_{17}H_{17}NO_2$) is very slightly narcotic. (e) **Papaverine** ($C_{20}H_{21}NO_4$) is also not very active. It is evident, therefore, that opium, which may contain more or less of all of these substances, must have an action on the body of a very complicated character.

Apomorphine ($C_{17}H_{17}NO_2$), a derivative of morphine, has none of the characteristic actions of that substance, but acts chiefly as a muscle- and nerve-poison, and as an emetic.

3. **Strychnine** ($C_{21}H_{22}N_2O_2$)—the alkaloid of *Strychnos nux-vomica*. In the frog very minute doses cause general convulsions, excited by peripheral irritation. These convulsions are due to the action of the poison on the spinal cord, as they persist after decapitation. In warm-blooded animals the reflex character of the convulsions is less evident; they have more of a tonic character, and chiefly affect the extensors. The poison heightens the reflex sensibility of the cord, acting especially on the anterior cornual cells. Death is usually the result of asphyxia from arrest in spasm of the respiratory mechanism, but it may result from exhaustion. **Brucine** ($C_{23}H_{26}N_2O_4$), another substance found in *nux-vomica*, has an action like that of strychnine, but more feeble.

4. **Atropine** ($C_{17}H_{23}NO_3$)—the chief alkaloid of *Atropa belladonna*. In the frog it causes tetanic reflex spasms after an interval of paralysis. Herbivorous animals, as a rule, have a tolerance of this poison, so that its effects are best studied in carnivora. Even in these the action is somewhat uncertain. Respiration may be paralysed without general convulsions; the pulse is quickened, from paralysis of the inhibitory action of the pneumogastric nerve on the heart; and the arterial pressure is increased. After very large doses the arterial pressure may be diminished, with paralysis of all parts containing involuntary muscular fibre. Secretions are greatly diminished. The pupil is dilated—apparently by a direct influence of the poison on the centres or nervous arrangements in the iris itself, as the effect may be observed even in an eye removed from the head. **Hyoscyamine** ($C_{17}H_{23}NO_3$) and **Hyosine**, the alkaloids of *Hyoscyamus niger*, and **Daturine**, the alkaloid of *Datura stramonium*, have actions allied to that of atropine, as well as the same formula.

5. **Digitalis** leaf contains at least three active principles—digitalin, digitalein, digitoxin—having the typical action of the drug on the circulation. The formulæ for these are at present unknown. A small dose of any one of these causes slowing of the heart and contraction of the arterioles with great rise of blood-pressure. If the dose be increased, the heart is arrested in diastole, and will not respond to direct excitation. These effects are brought about by an action on the muscle of the heart and small vessels, combined with a stimulant action on the vagus and possibly also on the intracardiac ganglia. It exerts a potent action on voluntary muscle, which, after small doses, becomes feebler in contractile power, while large doses may abolish contractility altogether.

6. **Physostigmine** or **Eserine** ($C_{15}H_{21}N_3O_2$)—the active substance of *Physostigma venenosum*, or Calabar bean. As has been pointed out by Professor Fraser, this alkaloid has an action antagonistic to that of atropine. Sensibility and consciousness remain until death; the voluntary muscles are paralysed, but previously they and the

involuntary muscles show tetanic contractions; respiration is at first accelerated, and afterwards slowed; the vessels become alternately dilated and contracted; secretion, especially that from the lachrymal and salivary glands, is increased; and the pupil is contracted. Physostigmine appears to paralyse the anterior cornua of the spinal cord.

7. **Curare**—a watery vegetable extract containing an alkaloid, **Curarine**, of the composition ($C_{18}H_{35}N$), obtained from certain parts of South America, and used by the natives of these regions as an arrow-poison. It is obtained from one or more plants belonging to the genus *Strychnos*. Its distinctive physiological action is abolition of the power of all voluntary movement, in consequence of its action, as was proved by Claude Bernard, upon the peripheral terminations of motor nerves—the 'terminal plates' of muscle. Respiratory movements are arrested as the result of paralysis of the muscles of respiration, but the heart may continue to beat for a considerable time. If artificial respiration be established, the circulation may be maintained for several hours, while the animal is completely under the influence of the substance. All the secretions are increased, and the mean temperature falls.

8. **Muscarine** ($C_8H_{15}NO_2$)—the alkaloid of *Agaricus muscarius*. It causes arrest of the heart's action in diastole, an effect which may be removed by the influence of atropine, thus affording an instance of physiological antagonism. In warm-blooded animals muscarine slows the heart's action; the blood-pressure falls; respiration is first embarrassed, and may be completely arrested; parts containing involuntary muscle are in a state of tetanic spasm; the pupil is contracted; and secretion is increased.

9. **Santonin** ($C_{15}H_{18}O_3$)—the neutral crystalline principle of *Artemisia maritima*. This drug may cause nausea, vomiting, hallucinations, vertigo, and a peculiar state of visual sensation—the field of vision usually appearing yellow, but sometimes violet. It is said that the stage of violet rapidly passes into that of yellow, and therefore it is probable that santonin may first excite the retinal fibres sensitive to violet (according to Thomas Young's theory of colour-perception), and afterwards paralyse them. In large doses, santonin causes loss of consciousness, tetanic convulsions, and death.

10. **Ergot**.—The active principles of Ergot have only been obtained in an impure state. The one which causes contraction of the small arteries and probably also of the uterus has been called *Sphacelinic Acid*; another which causes spasm has received the name of Ergotin (C₁₇H₄₀N₂O₆). Many others have been described. Ergot causes contraction of the smaller blood-vessels, contraction of the uterus, and slowing of the pulse; the animal may die in consequence of arrest of the action of the heart.

11. **Quinine** ($C_{20}H_{24}N_2O_5$)—one of the alkaloids of Cinchona. In small doses quinine accelerates the heart in the warm-blooded animal; in moderate doses it slows it; and in large doses it may arrest it, and cause convulsions and death. Research shows that its action is essentially upon the central nervous system. It destroys all microscopic organisms, killing vibrios, bacteria, and amæbæ. It arrests the movements of all kinds of protoplasm, including those of the colourless corpuscles of the blood. It arrests fermentative processes which depend on the presence of animal or vegetable organisms, but it

does not interfere with the action of digestive fluids.

12. **Nicotine** ($C_{10}H_{14}N_2$)—the alkaloid of Tobacco. It stimulates and then paralyzes the secretory nerves of glands, and also the nerves of involuntary muscles. It causes cold sweats, a feeble circulation, and fainting; a large dose causes death by failure of respiration, attended by severe convulsions. The blood-pressure falls at first, but it may then rise, and the pulse-rate is rapid. Nicotine first stimulates and then paralyzes the ends of the vagi in the heart.

13. **Cocaine** ($C_{17}H_{21}NO_4$)—from *Erythroxylon coca*. This is a local anæsthetic, acting on the terminations of the nerves of the skin and of mucous membranes. Its general action resembles that of caffeine, in small doses lessening fatigue, in larger doses causing wakefulness, or excitement and inability to think clearly. Its action is first on the cerebrum, then on the medulla, and lastly on the spinal cord. Very large doses may cause convulsions, of cerebral origin, or due to paralysis of the respiratory centre; the sensory columns of the cord are paralysed, while the motor are unaffected. Small doses raise the blood-pressure and quicken the pulse; large doses have the reverse effect. The secretions are generally diminished.

14. **Pilocarpine** ($C_{11}H_{16}N_2O_2$)—from *Pilocarpus pennatifolius* (Jaborandi). Pilocarpine stimulates the secretory nerves of glands, causing especially copious secretion from the salivary and sweat-glands. It also increases the secretion from the bronchial mucous membrane, from the glands of the stomach and intestines, and from the kidneys. It does not increase the secretion of bile, and its action on the mammary gland is uncertain. In large doses it may cause unsteadiness of movement, with a tendency to rotate, twitches of muscles, shivering, and dyspnoea, showing an action on nerve-centres. In these circumstances the pupils contracted, and there is indistinct vision, from spasm of the ciliary muscle. Large doses paralyse the vagus-endings in the heart, and there may also be spasmodic contractions of the muscular walls of the stomach, intestines, and bladder. During profuse sweating the temperature rises. There may be death from sudden collapse.

15. **Strophanthin** ($C_{21}H_{48}O_{12}$)—the active principle of *Strophanthus hispidus*. It resembles digitalin in its general action: it stimulates all striated muscles; in large doses, it may arrest the heart in systole; and it also acts as a diuretic.

16. **Acetanilide** (C_8H_9NO), **Phenazone** ($C_{11}H_{12}N_2O$), and **Phenacetin** ($C_{10}H_{13}NO_2$) depress the grey matter of the cord and brain, and thus diminish painful sensations. They also lessen a febrile temperature. In large doses they may cause collapse from extreme depression of the nerve-centres and an action on the hæmoglobin of the red blood corpuscles. JOHN G. MCKENDRICK.

ALKAPTONURIA (alkaptone; *οὐρον*, urine).—This very rare abnormality is characterised by the passage of urine which becomes brown and ultimately black on exposure to air, and much more rapidly on the addition of an alkali. The urine reduces Fehling's solution, and deeply stains any linen or woollen fabric with which it comes in contact. The condition, of which less than forty cases have, up to now, been recorded, is usually congenital and persists throughout life. It is apt to

occur in several members of a family. It apparently in no way detrimental to health, and is chiefly inconvenient on account of the staining of clothes, or as an obstacle to life insurance, since it is readily mistaken for glycosuria. The peculiarities of the urine depend upon the presence in it of homogentisin (hydroquinone-acetic) acid, $C_6H_5(OH)_2CH_2COOH$, but a second aromatic acid, uroleucic, $C_9H_{10}O_5$, has also been occasionally present. The essential fault appears to be a perversion of tyrosin-metabolism, for the administration of tyrosin by the mouth, although it does not cause alkaptonuria in normal individuals, greatly increases the output of homogentisinic acid in these cases. See LIFE ASSURANCE.

A. E. GARROD.

ALLANTIASIS (ἀλλὰς, forced meat).—Sausage-poisoning. See POISONOUS FOOD.

ALLEGHANY SPRINGS, in Montgomery county, Virginia, U.S.A.—Calcic or earthy waters. See MINERAL WATERS.

ALLEVAUD, in France (Isère).—Sulphur waters. See MINERAL WATERS.

ALLOCHIRIA (ἄλλος, another; and *χείρ*, the hand).—A peculiar disturbance of cutaneous sensibility in which a tactile sensation is referred to another part of the body than the seat of actual impression; or to a corresponding part of the opposite side of the body. See SENSATION, Disorders of.

ALOPECIA.—See BALDNESS.

ALOPECIA AREATA (ἀλώπηξ, a fox).—SYNON.: *Area*; *Alopecia circumscripta*; *Porrigo decalvans* Fr. *Alopécie*; Ger. *Fuchsräude*.

DEFINITION.—An atrophic disease of the hair, distinguished by the rapid development of more or less circular bald patches; in rare cases the baldness is general.

SYMPTOMS.—Alopecia areata is most common on the scalp, and is generally limited to that region, the occiput being the part most frequently affected. In some instances the beard and eyebrows suffer, and in very rare cases the whole of the hair is lost. Alopecia areata is usually confined either to a single round perfectly bald spot, or to several spots irregularly scattered about the scalp; when, however, the disease attacks the occiput, it is often roughly symmetrical. The same remark applies when the eyebrows and eyelashes are affected, and in all severe cases, which have a tendency to become symmetrical. A characteristic feature of the disease is the rapidity with which the hair falls off over a limited area, leaving very few, if any, stumps on the bald patch, which is bounded by hair of apparently natural growth. When, however, the hair round the area comes out very easily, it may safely be predicted that the spot will increase in size. The part affected is smooth and sometimes pinker than the surrounding skin, but much more commonly it is of the same colour, or paler. There is sometimes a slight atrophy of the skin, as well as of the hair, so that the area has a shallow, cupped character; this is comparatively rare, and therefore cannot be due simply to the loss of hair.

ÆTIOLOGY AND PATHOLOGY.—The causes of alopecia areata are obscure. The immediate origin of the disease is probably some nerve-disturbance, leading to atrophy of the roots of the hair and rarely also of the skin. This view is confirmed by the fact

that there is occasionally, though rarely, a temporary loss of sensibility over the area, and even when this is not the case, the skin is less sensitive to irritants than is normal. Sometimes the loss of hair is preceded by neuralgic pains, or tenderness on pressure, but more commonly there are no subjective sensations. The disease is rather more common in childhood and youth than in middle life, while it is seldom seen in old age; the writer has, however, met with one case in a man over seventy years of age who completely recovered. Alopecia is probably equally common in males and females, though on this point there is some difference of opinion. The old idea that the disease was due to a parasitic fungus is still common; but many of the clinical features of the disease, especially its great liability to recur after complete absence for perhaps years, is not at all in accordance with a parasitic origin. There is certainly sometimes a family tendency to alopecia. In extreme cases of alopecia areata, in which all the hair is lost, the nervous origin of the disease is generally admitted. Sabourard has found no less than fifteen species of micro-organisms in cases of alopecia areata, all of which he regards as casual denizens having no ætiological relation to the disease.

Radcliffe Crocker remarks, 'No one hypothesis will explain all cases, and the clinical facts can only be accounted for by explaining some cases on a trophoneurotic supposition and others on a parasitic.'

With regard to its morbid anatomy, it may be said that it is often difficult to find stumps, but when present they are very characteristic. They are also sometimes valuable for the purpose of differential diagnosis, since they are unlike the stumps of ringworm, being straight and thicker at the free end than at the point of insertion, which is contracted into a sort of neck, ending in a small rounded atrophied root looking like a note of admiration sign, !. A very slight amount of traction removes them entire; in this respect they differ much from ordinary ringworm-stumps.

DIAGNOSIS.—Ringworm is the only disease which is liable to be mistaken for alopecia areata. The difficulty arises thus: in common ringworm, either from treatment or from some unknown cause, the hair sometimes falls rapidly off, instead of breaking as it usually does. When the hair comes out in this way, with root attached, a smooth bald spot is left, exactly like alopecia areata; under these circumstances, unless a stump can be obtained for examination, the diagnosis is very difficult. The presence of other cases of ringworm in the same house, and the history of the patient, may be a guide to diagnosis.

Dr. Crocker mentions a very interesting and instructive series of cases of 'eight children in one family, who, while at the seaside, had each a few small perfectly bald spots on their heads; they were quite bare from the first, and never larger than half an inch in diameter.' After a time the governess contracted the disease, which was believed by her doctor to be alopecia areata, and not contagious; she, however, slept with her sister, who afterwards showed similar spots. Dr. Crocker says: 'The hairs round were loose; there were no short hairs, but one pulled out of the border showed distinct fungus-elements, indistinguishable from tinea tonsurans. In no case were there more than three spots, and they were all small. In one child there was a history of a red ring on the side of the cheek.' The

writer has himself met with three similar examples. The first was in a school of about forty-five girls, where there were upwards of twenty girls affected with small bald spots on the head, mostly free from stumps; there were, however, in a few cases a sufficient number of stumps full of ringworm-fungus to make the diagnosis certain. The medical officer to the school correctly diagnosed ringworm, although the appearance of most of the children would have deceived any one had the cases occurred singly. The second instance was in a boys' school, in which sixteen or seventeen cases of bald spots on the head occurred. The writer saw in the first place only two boys, who were sent to him before it was known that any others in the school were affected. Both boys had small bald spots like area, but on one of the spots were ringworm-stumps. The writer recommended that all the boys in the school should have their heads examined; this was done, and then many others were found to have bald spots. He subsequently saw one or two other boys from the same school with bald spots, which he had no doubt, under the circumstances, were ringworm. In this instance the disease had been called alopecia areata, and pronounced not contagious. The third case was in a family of children.

In all these cases there was a very close resemblance to 'area,' so that it would be almost impossible to diagnose an isolated case as tinea tonsurans, unless some of the affected hairs remained. In ringworm, when the hairs have all been shed, the risk of further contagion is much diminished; on the other hand, the disease spreads very rapidly at first, for every hair that is shed is a centre of infection. Syphilitic alopecia may resemble alopecia areata very closely. The hair on the rest of the scalp is, however, generally scanty, and some evidence of syphilis usually coexists elsewhere.

TREATMENT.—The prognosis in most cases of alopecia areata is favourable, depending on the duration of the trouble, but the disease is very tedious. In the neurotic form the new hair is frequently white, and remains so for a long time. The treatment is partly local and partly general; the local treatment consists in the application of stimulating remedies to the bald patch, of which the best is cantharides. The acetum cantharidis, diluted with one or two parts of spirit, and painted on daily with a camel's-hair brush, answers very well. The lotion used should not be strong enough to blister, because its daily use cannot then be continued. Capsicum, oleum pini, perchloride of mercury, and faradism find favour with some dermatologists. A stimulating parasiticide, as chrysarobin ointment (5j to ʒj lanolin), is most useful, but its employment has drawbacks. The general treatment should consist of suitable tonics, and wine or beer, with plenty of rest and bracing air. Continued physical fatigue appears in many cases to favour the development of alopecia areata.

ROBERT LIVEING.

ALPHOS and ALPHOIDES (ἀλφός, white).—Terms signifying white and white-looking, associated with the whiteness of the scales of common psoriasis: hence *lepra alphos* and *lepra alphoides*. See PSORIASIS.

ALPHOSIS (ἀλφός, white).—Whiteness, or the process of turning white. See ACHROMA.

ALTERATIVES.—**DEFINITION.**—Medicines which gradually restore the nutrition of the body to

a healthy condition, without producing evacuations, or immediately exerting any very evident action upon the nervous system.

ENUMERATION.—The principal alteratives are—Nitric and Nitro-hydrochloric acids; Chlorine and Chlorides; Iodine and Iodides; Sulphur and Sulphides; Potassium and its salts; Mercury and its salts; Phosphorus and Hypophosphites; Antimony; Arsenic; Taraxacum; Sarsaparilla; Hemidesmus; Guaiacum; Colchicum; and Mezereon.

ACTION.—Healthy nutrition depends on the digestion of the food, its assimilation by the tissues, the decomposition of the tissues during the exercise of their functions, and the removal of their waste products being performed in a proper manner—in due proportion one to another. If the food is not properly digested, as in dyspepsia; or is not properly assimilated, as in diabetes; or if the tissues break up too rapidly, as in fever; or if the waste products are not properly removed, as in some cases of kidney-disease, nutrition suffers. Digestion and excretion may be improved by tonics, purgatives, and diuretics; but alteratives seem to exert their action upon assimilation and tissue-change. The digestion of food is effected by means of ferments, such as those of the salivary glands, stomach, pancreas, &c. Some also of the changes, such as the conversion of glycogen into sugar, which the food undergoes after absorption in the liver, and even certain so-called vital actions—such as the coagulation of the blood—are produced by a similar agency. It is not improbable that the histolytic changes in the tissues are also effected by ferments. They do not depend upon oxidation, for although during health the products of tissue-decomposition are oxidised as fast as they are formed, yet under certain circumstances the tissues are split up so rapidly that the products which they yield are only partially oxidised. This is seen in poisoning by antimony, arsenic, and still more markedly by phosphorus, where such tissues as the muscles become decomposed, yielding nitrogenous substances, such as leucin, tyrosin, or urea, and fat. The former are excreted in the urine; while the last, instead of undergoing combustion, accumulates in the place formerly occupied by the muscular tissue, which is accordingly said to be in a state of fatty degeneration. It is possible then, although by no means certain, that alteratives influence nutrition, either by modifying the activity of ferments, or by altering the susceptibility of the tissues to their action.

Mercurials in purgative doses, taraxacum, nitric and nitro-hydrochloric acids, probably act by modifying the digestion of the food in the upper part of the small intestine, or by affecting the changes which it undergoes in the liver after absorption. Potash has probably an action on the muscles. Antimony, arsenic, and phosphorus especially affect the nervous and cutaneous systems. Mercury has a peculiar power of breaking up newly formed fibrinous deposits, and particularly syphilitic growths. Iodine, iodides, and probably chlorides, act upon the lymphatic system and promote absorption.

USES.—Purgative doses of mercurials, taraxacum, nitric and nitro-hydrochloric acids are useful in cases of frontal headache, general malaise, and depression of spirits, associated with symptoms of so-called biliousness, or with the appearance of urates or of oxalates in the urine. Potash and colchicum are employed in the treatment of gout. Phosphorus

and arsenic are used in cases of nervous debility, as well as in nervous diseases, such as neuralgia and chorea, in which antimony is also serviceable. Arsenic is also given in diseases of the skin; and antimony in inflammation of the mucous membrane of the bronchi. Mercury in alterative (that is, small) doses, which are absorbed into the circulation without purging, is used to break up newly deposited fibrinous masses, as in iritis, pericarditis, &c., and to counteract the effect of syphilitic virus upon the soft tissues in the secondary stage of this disease. Iodine and iodides act on the lymphatic system, and are useful in removing glandular swellings. By stimulating the absorbent system they may also assist in the removal of the fibrinous deposits and syphilitic growths disintegrated by mercury. The iodides are sometimes given in the secondary, but are still more valuable in the tertiary, stage of syphilis.

T. LAUDER BRUNTON.

ALVENEU, in Switzerland.—Sulphur waters, and chalybeate water, with iodine and common salt. See MINERAL WATERS.

ALVEOLAR.—A word used in pathology as descriptive of any morbid growth which consists of small cavities or spaces (*alveoli*), usually occupied by cells, and bounded by walls formed of cells or fibres. See CANCER.

AMAUROSIS (ἀμαύρωσις, a darkening or dulling of the sight).—The term ‘amaurosis’ has now almost fallen into disuse. It was originally employed, before the use of the ophthalmoscope became general, to denote partial or total blindness unaccompanied by any obvious change in the eyeball. The large majority of cases formerly called amaurotic are now more accurately classified. See EYE and its APPENDAGES, Diseases of; vii. Diseases of the OPTIC NERVE and RETINA.

AMBLYOPIA (ἀμβλωπία, dim-sightedness).—Obscurity of vision.

AMBULANCE (*ambulo*, I move about).—**SYNON.** : Fr. *Ambulance*; Ger. *Feldlazareth*.

DEFINITION.—A term adopted from the French word, which signifies the movable hospital of an army.

The use of an ambulance is to convey from place to place those who are sick, wounded, or otherwise incapable of moving.

DESCRIPTION.—An ambulance consists of a *vehicle* or caravan, upon or within which one or more *stretchers* can be laid or fixed.

Stretchers.—It is important that stretchers should be of uniform pattern, so as to admit of easy transference from one carriage to another. Each stretcher consists of two poles kept apart by metal traverses, supporting a canvas stretched between. The length of a stretcher (7ft. 9in.) is often inconvenient when conveying a patient through passages or up staircases. To obviate this difficulty, the poles of stretchers used for civil ambulances should be made of metal tube capable of being telescoped.

The *vehicles* or carriage-frames are of two kinds : (1) those for *hand-ambulances*; and (2) those for *horse-ambulances*.

1. *Hand-ambulances*, or litters, of which there are several varieties, consist of a skeleton carriage, firmly supported on easy springs, and provided with two, three, or four wheels.

Upon a framework thus formed, the stretcher fits, and is immovably fixed by straps or bolts. The carriage is made with a view to convenience of size and lightness of structure, consistently with strength. Facility in turning should be secured. A complete covering or hood protects the patient from exposure. In all ambulances special care should be taken, by springs and other contrivances, to prevent the suffering caused by jolting.

2. *Horse-ambulances* are used for (a) civil, and (b) military purposes.

(a) The first of these, as used in towns, are drawn by one horse. They usually consist of coaches which are unlined, so as to allow of washing and complete disinfection. One or two doors are placed behind, through which a stretcher or bed may slide on to a shelf, occupying about one lateral half of the interior of the coach. A seat for an attendant completes the fittings.

Ambulances for civil purposes should be easily obtainable at hospitals, police-stations, and other recognised centres.

(b) *Military ambulances*, more commonly termed ambulance-wagons, are of many different patterns. They consist of a wood-framed body provided with a cover, curtains, and hood of canvas extended on a skeleton-framed roof. They carry likewise a reservoir for water. These ambulances are drawn by two or more horses. In the English army they are generally arranged to carry two patients on stretchers, and five others less seriously injured, two in front and three behind. In the German army they accommodate four stretchers—two on the floor of the wagon, and two on a plane above—besides five other persons slightly wounded.

In war the ambulance-wagons are never sufficiently numerous to meet the demands arising after a heavy battle; in such emergencies, farm wagons and carts of the country are therefore requisitioned and the wounded are laid upon a bed of straw.

Ambulance Field Hospital.—Captain Tomkins, of the Victoria Rifles, and the writer have designed an ambulance-wagon which supports on its exterior a folding double tent 35 x 22 feet. Twenty folded stretchers, each convertible into a bedstead, one foot high by two feet two inches wide, line the side of the wagon. There are also provided the requisites for twenty beds, surgical instruments and appliances, a furnace for cooking, and for warming the tent in winter, together with rations for three days. This arrangement obviates the necessity for assistance from the main army.

A. T. NORTON.

AMBULANT (*ambulo*, I move about).—Moving, unfixed, shifting. Applied to diseases that shift from one part to another, such as erysipelas; in connection with blisters applied in succession to different parts of the body, also called 'flying blisters'; and to moving or 'field' hospitals, as distinguished from fixed or 'base' hospitals.

AMBULATORY (*ambulo*, I move about).—A term used in connection with mild or latent cases of acute diseases, in which the patient continues to walk about, or work, up to a late period of the attack, as in typhoid fever—*typhus ambulans s. ambulatorius*. See TYPHOID FEVER.

AMÉLIE-LES-BAINS, in France (Pyrénées). Thermal sulphur waters and climatic health-

resort. See MINERAL WATERS, and CLIMATE, Treatment of Disease by.

AMENORRHOEA (ἀ, priv.; μήν, a month; and ῥέω, I flow).—Absence of the menstrual flow during any portion of the period of life when it ought to be present. See MENSTRUATION, Disorders of.

AMNESIA (ἀμνησία, forgetfulness).—SYNON.: Fr. *Amnésie*; Ger. *Gedächtnisschwäche*.—A general term signifying loss or defect of memory; commonly, however, used in reference to one particular class of defect of memory, viz. that for words (*amnesia verbalis*). Sometimes there is a mere forgetfulness of proper names; sometimes a substitution of wrong words; at other times the pronunciation of a meaningless jargon, not at all representing words. The production of these defects is due to disease in different parts of the brain, owing to the memories of words being threefold—auditory, visual, and kinæsthetic. See APHASIA.

AMCEBA COLI.—A species of amoeba, found in connection with ulceration of the colon and with tropical abscess of the liver. See DYSENTERY; and LIVER, Abscess of.

AMPHORIC.—A peculiar hollow, metallic quality of sound, elicited occasionally by percussion, but more commonly heard in auscultation. Amphoric breath-sound resembles that produced by blowing into an empty glass or metallic vessel with a narrow neck (*amphora*). See PHYSICAL EXAMINATION.

AMYLOID DISEASE (ἄμυλον, starch).—SYNON.: *Lardaceous Disease*; *Albuminoid Disease*; *Waxy Degeneration*. Fr. *Dégénération amyloïde*; Ger. *Amyloide Entartung*; *Speckartige Degeneration*.

DEFINITION.—A condition characterised by a peculiar degeneration of the cells of certain organs, whereby a substance known as amyloid or lardacein is produced.

ÆTIOLOGY.—The most frequent cause of this condition is protracted suppuration from a deeply seated focus, such as diseased bone, or from a cavity not admitting of effectual drainage. Hip-disease, empyemata, and chronic pulmonary tuberculosis are thus frequent antecedents of amyloid degeneration. It also occurs in tertiary syphilis and in the hereditary form of this disease, apart from any suppuration, and occasionally in cases of dysentery, malaria, leuchæmia, and malignant tumours. Very rarely it appears to be a primary disease, especially in children. Amyloid degeneration is met with as a merely local change in the neighbourhood of syphilitic gummata.

The formation of amyloid substance is probably due in all cases to the action of toxins produced by micro-organisms. This is suggested by its association with ill-drained cavities rather than with profuse but unimpeded suppuration, and is confirmed by the experimental induction of the change by inoculating animals with cultures of the *Staphylococcus pyogenes aureus*. In cases of suppuration experimentally produced the appearance of the degeneration may be exceedingly rapid. Amyloid substance is very resistant to putrefaction and to the action of digestive ferments. Chemically it is stated to be a compound of an organic acid (chondroitin-sulphuric acid) with some form of albumen (Krawkow). It is probable that this latter component may vary

somewhat in different specimens, and that thus slight differences of behaviour to reagents may be accounted for.

ANATOMICAL CHARACTERS.—The organs principally affected by amyloid degeneration are the liver, spleen, kidneys, intestine, and lymphatic glands; more rarely the other digestive organs, the generative organs, muscles, serous membranes, and cerebro-spinal meninges may be involved. The change is primarily confined to the connective tissue; it is doubtful whether epithelial cells ever undergo this transformation. Affected organs are enlarged, pale and bloodless, firm in consistency, with smooth surfaces and somewhat thickened rounded edges. On section they present in advanced cases a peculiar glistening appearance, as if dotted with small masses of transparent material. Early stages of the change can only be recognised by the *characteristic colour-reactions*; if the cut surface of an amyloid organ be washed and treated with a weak solution of iodine, the degenerated parts assume a mahogany-brown hue, while the healthy tissue is stained a pale yellow. For microscopic purposes sections are stained with methyl- or gentian-violet, excess of the dye being washed out with dilute (10 per cent.) acetic acid: thus treated the amyloid masses are stained a magenta colour, the normal tissue appearing blue. If sections be stained with iodine and mounted in glycerine, the addition of a drop of strong sulphuric acid placed at the edge of the cover-glass will produce a blue or greenish-blue coloration in the amyloid substance.

In the *liver* the degeneration affects principally the capillaries of the hepatic artery, and therefore appears first in the middle zones of the lobules. The liver-cells are pressed upon by the new material, and become fatty and finally disappear. In very rare cases the capillaries of the portal vein may be affected, and ascites may ensue. In the *spleen* the disease may affect either the Malpighian bodies alone, which then resemble grains of boiled sago set in the substance of the organ (sago-spleen), or the connective tissue forming the trabecule (diffuse form): rarely both forms occur together (mixed form). In the *kidneys* the glomeruli generally suffer early, and along with them the middle coat of the smaller arteries is invaded; later the larger arteries, the intertubular tissue, and the tunicae propriae of the tubules also suffer. A certain amount of tubal nephritis generally accompanies the degeneration, being due either to pressure and irritation caused by the masses of amyloid material or to the action of the same toxins which cause the degeneration. Casts are formed in the tubules, and it is said that they may give the characteristic amyloid reaction with iodine; more frequently they are either hyaline cylinders or covered with fatty or granular epithelium. In the *intestine* the vessels running in the centres of the villi are chiefly affected, so that treatment with iodine causes the interior of the gut to appear stippled with closely set brown dots.

EFFECTS.—The effects of amyloid degeneration of the liver and spleen cannot be distinguished from those of the primary condition from which the patient is suffering, though there can be little doubt that the general constitutional disturbance is aggravated by the degeneration of these organs. If the intestine is affected, severe and uncontrollable diarrhoea results, probably due to increased transudation of serous fluid through the affected vessels. Ulcers may also be formed in the

intestine, apparently by rubbing off of villi rendered brittle by the change. In the kidney increased transudation leads to polyuria and to the appearances of albumen in this secretion. It is here often difficult to distinguish the respective parts played by amyloid change and by the accompanying tubal nephritis.

CLINICAL CHARACTERS.—Patients suffering from secondary amyloid disease are weak, anæmic and emaciated. The abdomen is often enlarged owing to the increase in size of the liver and spleen, which may together occupy a large portion of this cavity. Ascites is exceptional, and there is not often pain in the affected organs: when pain occurs it is probably due to the weight thrown upon their attachments or to slight accompanying peritonitis. The enlarged organs are smooth and firm on palpation and not generally tender. In primary cases and in amyloid disease affecting the kidneys alone (frequently syphilitic) there is less emaciation and debility, but anæmia is constant. The urine is pale and abundant, and contains an amount of albumen which increases as the disease advances. The occurrence of subacute attacks of tubal nephritis may cause the urine to be temporarily scanty, high-coloured, and even bloody: in such cases uræmia may result. The intestine is generally affected late in the disease.

DIAGNOSIS.—Enlargement of liver and spleen occurring in leucæmia, in cirrhosis of the liver, and in children the subjects of rickets or congenital syphilis, have to be distinguished from amyloid disease. In most cases of this degeneration the existence of suppuration in some part gives a clue to the nature of the condition. If any question of leucæmia arise, it should be borne in mind that suppuration may be associated with some increase in the number of leucocytes present in the blood, but that in such a case the additional white corpuscles will be of the multinucleated variety. The existence of amyloid disease of the kidney alone must practically be inferred by a process of exclusion. A history of syphilis or signs of this disease may be of assistance as pointing to a cause of amyloid change. The form of renal disease for which the amyloid kidney is most likely to be mistaken is the contracting large white kidney: the presence of œdema is in favour of the inflammatory condition, but the supervention of tubal nephritis upon the degenerative process may make the existence of the latter impossible to recognise.

PROGNOSIS.—If the cause of the amyloid degeneration can be removed, it is rendered fairly certain by the results of experiment that the local change may disappear. Unfortunately the removal of the cause may often be impossible, and in such cases it is unlikely that the patient will survive the appearance of amyloid disease for more than two years. Many cases terminate fatally at a much earlier period. The occurrence of diarrhoea, showing implication of the intestine, indicates that the fatal issue will not be long delayed. In syphilitic cases the outlook is less unfavourable, and recovery may take place under appropriate treatment.

TREATMENT.—The treatment of amyloid disease must be directed mainly to the primary cause. Towards prevention of its occurrence much has been done by antiseptic methods of surgery, both in lessening the number of cases which suppurate and in checking suppuration when it has occurred. Even after amyloid change has set in every attempt

must still be made to treat the pyogenic focus by the most radical methods available. The patient must in all cases be placed in the most favourable conditions. Carefully regulated nutritious diet is indispensable: sea-air and sunshine are valuable auxiliaries. Cod-liver oil, malt-preparations, hypophosphites, and iron are useful remedial agents. In syphilitic cases iodide of potassium must be given in full doses. Care must be exercised in prescribing any preparations of mercury to patients who are the subjects of renal lesions. For the diarrhoea due to the intestinal affection, opium, bismuth, and other astringents may be tried, but the condition is seldom amenable to any form of treatment.

WM. CECIL BOSANQUET.

AMYOTROPHIC (ἀ, priv.; μῦς, a muscle; and τροφή, nutrition).—Associated with muscular wasting. See SPINAL CORD, Diseases of.

ANÆMIA (ἀ, priv.; and αἷμα, blood).—SYNON.: *Spanæmia*; *Hydræmia*; *Oligæmia*; Aglobulism. Fr. *Anémie*; Ger. *Anämie*; *Blutarmuth*.

DEFINITION.—Deficiency, absolute or relative, of the most important constituents of the blood, particularly albuminous substances and red corpuscles.

This definition is purely pathological, and the condition thus expressed presents many varieties, anæmia in the widest sense of the term including oligæmia, oligocythæmia, hydræmia, and spanæmia, as well as chlorosis (see CHLOROSIS; and BLOOD, Morbid Conditions of). From the clinical point of view, anæmia is a condition of system in which impoverishment of the blood, whether from want or from waste, is associated with symptoms of imperfect discharge of the vital functions.

ÆTIOLOGY.—The causes of anæmia are generally multiple and complex. First, the supply of blood to the body may be insufficient, and that from a variety of causes, of which the chief are:—derangements of alimentation, including insufficient food, constipation, and morbid states of the lymphatic and blood-glands; such defective hygienic conditions affecting the formation and nutrition of the blood as want of light, air, and muscular exercise; prolonged exposure to the influence of certain poisons, as lead, mercury, and malaria; and, lastly, interference with the free circulation of the blood by cardiac or vascular disease, such as valvular disease or dilatation of the heart and aneurysm of the aorta. Secondly, the consumption of blood is increased by hæmorrhage; by profuse discharges, such as suppuration and albuminuria; by hæmolysis; by rapid growth and development; by frequent pregnancy and superlactation; by excessive muscular exertion; and by the presence of pyrexia, or of new growths, which rob the system of nutritive material. In a third group of cases of anæmia both the supply and the consumption are at fault. Thus derangement of the organs and of the whole process of sanguification is frequently associated with profuse discharges from various parts; and in acute febrile diseases, malignant diseases, and the 'chronic constitutional diseases,' such as syphilis, tuberculosis, Bright's disease, albuminoid disease, Addison's disease, and others, the cause of the anæmia is extremely complex. But the majority of the cases of anæmia that are regarded and treated as such fall into the class to which the name of *idiopathic* has been applied. In such cases the anæmic condition

is due, not to any disease so called, but to disturbance of nutrition generally—that is, of the healthy relation between the demands of the system and the supply of nutrient material. This condition occurs chiefly in children and young women, at the period of bodily growth and of the development and early activity of the sexual functions; and when, as so frequently and unfortunately happens, the air, food, occupation, and nervous relations of the individual are all more or less unwholesome.

ANATOMICAL CHARACTERS.—The blood suffers three principal changes in declared anæmia, namely: (1) increase or deficiency (oligæmia) in amount; (2) deficiency in red corpuscles or hæmoglobin (oligocythæmia, aglobulism); and (3) deficiency in albuminous constituents (hypalbuminosis). Of these oligæmia is the rarest, the total amount of blood being often increased (see CHLOROSIS). Aglobulism is a very early and common, as well as the most obstinate, change in the blood. Hypalbuminosis is the most advanced and perhaps the most serious alteration of the three (see BLOOD, Morbid Conditions of). The blood is watery and pale; has a diminished specific gravity; and coagulates slowly and loosely, or in aggravated cases not at all, settling into three layers—consisting respectively of red corpuscles, white corpuscles, and plasma. The body presents certain changes directly due to the state of the blood. Whether the anæmia be local or general, the corresponding parts are blanched and 'bloodless.' The cells of the tissues become atrophied and degenerate, in consequence of, and in proportion to, the interference with their plastic and functional activity respectively; and the so-called 'anæmic' form of fatty heart, liver, kidneys, and other organs is the result. If death occur suddenly from acute anæmia, the heart is found empty and contracted.

PATHOLOGY.—When the volume of blood in the body has been reduced by repeated small hæmorrhages, the phenomena that supervene, while they express the want of blood as a whole, and of its several constituents, are chiefly referable to the loss of two of these constituents—the albuminous substances and the red corpuscles or hæmoglobin, that is, of the oxidisable and the oxidising materials. The same effects will be produced by a drain of the liquid part only of the blood, or by poverty of the blood from any of the causes enumerated above, whether of the nature of waste or of want; inasmuch as loss of plasma speedily affects the nutrition of the red corpuscles. These phenomena constitute the symptoms of the anæmic condition whatever may be its cause; their relative prominence naturally varying according to an immense number of circumstances.

SYMPTOMS.—The subjects of anæmia are usually girls and young women. Their general appearance, which is striking, is one of pallor, debility, and variable loss of feminine fulness. The visible parts of the surface are pallid, often with a tinge of dusky brown on the eyelids and the backs of the hands; the clearness of the complexion varies with the normal pigmentation of the body; the skin is soft, satiny, and rather loose. The mucous surfaces also are blanched; the sclerotic is pearly blue. The loss of flesh may be moderate, or it may be considerable. The extremities are cold, and the legs and lower eyelids are often œdematous. Pyrexia is occasionally present, the temperature rising as high as 102° F. or even more. Bodily strength is

reduced; muscular force is diminished, while myalgia is common; an air of languor and want of vigour pervades the whole demeanour; and the patient is sleepy, dull, and depressed. The subject of anæmia generally complains of weakness, various pains about the body and head, and marked shortness of breath on the least exertion. The last symptom is unaccompanied by other evidence of respiratory derangement; in character the breathing is regular, and short or even panting. The symptoms referable to the circulation consist chiefly of palpitation on exertion; a tendency to faint; and pain or distress over the cardiac region. The physical signs indicate cardiac enlargement of variable degree. A rough systolic murmur is usually heard over the pulmonary artery; a soft systolic murmur at the aortic base, in the mitral area, possibly over the whole præcordia, and even at the scapular apex; the second sound is often universally accentuated. Over the cervical vessels a systolic murmur is commonly audible, followed by a sharp sound; in the neck a loud venous hum. The cervical vessels may throb; the radial pulse is small, weak, and of variable but usually increased frequency and suddenness. There is a tendency to hæmorrhages, especially epistaxis; and petechiæ are occasionally observed. The digestive system is markedly affected, as shown by loss or perversion of appetite; an anæmic, often clean, but variable tongue; dyspepsia, nausea, and sickness after meals or on rising; and constipation, which is present in the majority of cases, and is frequently prolonged and severe. The menstrual functions are almost always deranged: amenorrhœa is common, in some form; menorrhagia is rare (except as a cause of anæmia); dysmenorrhœa is frequently associated; and leucorrhœa is the rule. The urine varies greatly. Headache, tinnitus aurium, and other cerebral symptoms are common. There may be swelling of the optic disc. Blood drawn from the finger shows aglobulism. See BLOOD, Examination of.

COURSE AND TERMINATIONS.—The course of anæmia in this form is essentially slow and progressive, unless it is checked; the *duration* is perfectly indefinite. The course of the symptomatic form will naturally vary with its cause. Idiopathic anæmia rarely terminates fatally; and, when it does so, the event may be referred, with few exceptions, to some complication. Occasionally, however, it progresses steadily to death. See ANÆMIA, PERNICIOUS.

Intercurrent diseases may be expected to be severe in an anæmic condition, in proportion to its degree. See COMBINED DEGENERATION OF THE SPINAL CORD.

DIAGNOSIS.—Anæmia is generally recognised with the greatest ease, and the chief question of diagnosis relates to its *cause*. The first point to be determined, therefore, is whether it is not *symptomatic* of some more grave state, such as tuberculosis, syphilis, albuminoid disease, or some other of the many possible causes of poverty of blood. Having settled that the anæmia is *idiopathic*, we must next exclude two diseases with which it may be confounded, namely chlorosis and leuchæmia. Chlorosis, in which the plasma is not considered to be altered, and which possesses otherwise a special pathology, is expressed by the yellow tint of skin, by the absence of wasting and of dropsy, as well as by other features (see CHLOROSIS). The diagnosis of

pernicious anæmia is fully given in the article on that subject. Leuchæmia is recognised by examination of the blood and spleen. The starting-point of the blood-change in idiopathic anæmia can only be discovered by investigation of all the facts of the case.

PROGNOSIS.—The prognosis of anæmia is favourable as regards life. In simple anæmia from loss of blood, the patient may be assured of speedy and complete recovery. In idiopathic anæmia, however, this promise can be given only when the cause can be removed or avoided. Under favourable circumstances and judicious treatment, improvement will begin almost immediately; and health should be restored after a few weeks or months.

TREATMENT.—The treatment of anæmia, when it is symptomatic of some more grave condition, such as Bright's disease or phthisis, does not require notice here. When blood has been lost in serious quantity, without other injury of consequence, it will be naturally restored if but sufficient time be given, and interference otherwise avoided. Attention to the ordinary rules of health, abundance of food and air, and moderate exercise, will surely if slowly restore the patient, without the administration of a single drug. Even in this case, however, treatment may be of great service, by arresting, if necessary, the cause of the anæmia, such as menorrhagia or epistaxis; and by assisting nature, if the condition should threaten at any time to become intensified by its own effects.

But before the blood can be restored in the large and ill-defined group of cases known as idiopathic anæmia, the unhealthy influences under which the patient is placed, and the functional and other derangements which are usually accountable for the imperfect sanguification, must be discovered and corrected. Each case must be treated on its own merits, routine being avoided. Where the ætiology is complex, treatment must be equally general, and the whole system of life will have to be reformed. On the other hand, in the rapidly growing child and youth, and still more in girls at puberty, the great demand for nutritive material must be duly considered, and every obstacle to its supply removed. When other than direct discharges are draining the blood, they must be checked. Lactation may have to be forbidden; and leucorrhœa and spermatorrhœa will sometimes demand local treatment.

The removal of the cause being thus made the first element in treatment, means must next be adopted for the restoration of the blood. To accomplish this, it will be necessary to bring the alimentary tract and the organs of sanguification into a healthy state. Dyspepsia and constipation require immediate treatment. The best plan is to begin with a brisk purge, and to follow this up with a course of iron and aloes in pills every night, so as to secure one, and only one, daily evacuation of the bowels. Therewith a bitter and alkaline stomachic mixture may be given before meals for a few weeks. The food must be carefully ordered, so that it shall not only supply the albuminous elements that are specially deficient in the blood, but be retained, digested, and absorbed.

The process of sanguification may be successfully assisted by means of drugs. Iron is the sovereign remedy for aglobulism; and, practically speaking, it speedily becomes a question in the medicinal treatment of a case of anæmia in what form iron is to be given. The compound iron mixture of the pharma-

copeia, perhaps, answers more frequently than any other; but, on the one hand, when there is constipation, as is so often the case, combinations of aloes and iron in pill, or a mixture containing the protosulphate with purgative saline sulphates, will be more suitable for a time; on the other hand, when there is a tendency to discharges, the persalts with bitters, combined, if necessary, with sulphate of magnesium, will answer the purpose better. Compounds of iron with quinine or strychnine should be given in cases where less marked anæmia occurs in older subjects, with nervous depression and general want of vigour. In special cases the ferrum redactum, saccharated carbonate, or the vinum ferri (with compound decoction of aloes in constipated subjects), ammonio-citrate of iron, or Blaud's pill may be ordered. Some patients cannot take iron except in the effervescing form; others only if it is presented to them highly diluted—for instance, as a few drops of the tincture of the perchloride in a glass of water. To meet this difficulty, as well as to secure the benefit of many other recuperative influences, a course of chalybeate waters may be the best means that can be devised (see MINERAL WATERS). The addition of arsenic to the iron is invaluable in many cases; in other instances arsenic alone, given as Fowler's solution, proves eminently successful after iron has failed. According to some authorities, manganese assists the action of iron. Cod-liver oil is sometimes prescribed with success. Other symptoms must be treated on ordinary principles. Uterine complaints demand special attention; and bromides, ergot, opium, and other sedatives and astringents are indicated where excitement and excessive discharge are present.

While these dietetic and medicinal measures are being carried out, it is impossible to insist too strongly upon attention to bodily and mental hygiene: the use of the tepid morning bath; the proper disposal of time in relation to exercise, education, and amusement; healthy clothing, or rather 'dress'; the avoidance of unwholesome excitement; early hours; and sufficient sleep. In a large number of cases change of air fulfils many of these conditions. On the other hand, in acute anæmia, as well as in severe cases of every kind, rest in bed is imperative for a few days. Time is an essential element in the cure. A frequent change in the form of the medicinal remedies is also advisable.

J. MITCHELL BRUCE.

ANÆMIA, LYMPHATIC.—A form of anæmia which is associated with a peculiar affection of the lymphatic system. See LYMPHADENOMA.

ANÆMIA, PERNICIOUS.—**SYNON.** : Fr. *Anémie pernicieuse progressive*; Ger. *Progressive perniciose Anämie*.

DEFINITION.—A progressive hæmolytic process affecting both sexes, especially in middle life, characterised by fatty degeneration of the heart and retinal hæmorrhages, and in nearly all cases terminating fatally.

Pernicious anæmia includes two varieties: the primary, essential, or 'idiopathic anæmia' of Addison; and the deuteropathic, symptomatic, or secondary anæmia of German authors. The clinical symptoms in the two varieties are, on the whole, alike. Whilst it is possible that pernicious anæmia is really not a disease *per se*, but a group of symptoms, yet for clinical purposes these symptoms are constant enough to constitute a distinct disease.

ÆTIOLOGY.—Pernicious anæmia occurs about equally in men and women, unless we include all cases of fatal or severe anæmia secondary to uterine hæmorrhage. In women the disease is most frequently met with between the ages of 20 and 40 (the period of child-bearing), whereas in men it occurs most frequently between 40 and 60. The youngest age on record is 7, the oldest is 68. Although the disease is more common among country people than town-dwellers, this cannot be ascribed to their respective occupations.

Among the better classes the disease is uncommon; when it does occur, no cause can be ascertained, excepting, in a few instances, mental worry, grief, or fright. It occurs with especial frequency in countries the inhabitants of which are poor and insufficiently supplied with food, particularly nitrogenous food, and who live in small, over-crowded, badly lighted, and ill-ventilated houses. Repeated pregnancies, especially in women who are badly nourished or suffer from ordinary bloodlessness, are also a cause of pernicious anæmia. It seldom affects primiparæ. Excessive lactation, severe puerperal or other hæmorrhages, dyspepsia, and the uncontrollable vomiting frequently met with during pregnancy, are considered by many authors to rank as causes of the secondary form of this disease: some German authorities include parasites, such as the *Ankylostoma duodenale* and the *Bothriocephalus latus*. Malaria and yellow fever have also been antecedent to this form of anæmia; and Müller has called attention to the connection of constitutional syphilis with this disease. Septic infection has been urged as a cause of the disease, and William Hunter has recently called attention to the frequency with which patients suffering from this form of anæmia are the subjects of septic infection arising from carious teeth and stumps. He considers the disease to be a toxæmia, the result of a specific infection of the digestive tract, and the chief source of infection to be through the mouth in connection with long-continued cario-necrotic conditions of the teeth; sometimes possibly from stomatitis arising from other causes, e.g. drain-poisons.

ANATOMICAL CHARACTERS.—As a rule the body is not emaciated; indeed a thick layer of subcutaneous fat, of canary-yellow colour, is usually found. The muscles are of good colour. The heart and the great vessels contain but little blood; this is of a pale colour and often uncoagulated. The heart itself presents well-marked fatty degeneration, having the characteristic 'tabby cat' appearance. The fatty degeneration affects the ventricles more than the auricles, the left ventricle more than the right, and the muscoli papillares more than any other part. This is the most constant of the morbid anatomical conditions. The cavities are sometimes dilated; the valves are normal. Flecks of fatty degeneration are commonly seen affecting the intima of the large arteries, and the same change probably occurs in the capillary vessels, explaining perhaps the occurrence of petechiæ and retinal hæmorrhages. Small ecchymoses occur in the brain, serous membranes, and elsewhere. Passive effusions into the serous cavities are not uncommon.

All the organs of the body, with the exception of the spleen, look very pale, as if their vessels had been washed out with water. The liver is generally fatty, but is not much enlarged. The spleen may be normal, small, or somewhat enlarged, but never attains great dimensions, as in leucæmia. The

kidneys are pale, often showing slight fatty change. The mucous membrane of the stomach and intestines often exhibits hæmorrhagic erosions; and atrophy of the tubular glands of the former has been described.

The marrow of the bones may be normal, or the red marrow increased; in some cases the yellow marrow of the long bones has been replaced by red—probably a result of the disease rather than the cause of it.

SYMPTOMS.—The patient suffers from weariness, lassitude, headache, vertigo, and dizziness, with faintness, palpitation, and breathlessness on exertion. These symptoms make their approach in so slow and insidious a manner that the patient is unable to fix the date of their onset, and probably does not seek medical advice until he is incapacitated for mental or bodily work.

The aspect of the patient is characteristic: the mucous membranes are pale; the skin is usually of a light lemon-yellow colour, 'like white wax changed by age.' The conjunctivæ are white, though the presence of yellow fat beneath might lead a careless observer to believe there was slight jaundice. The patient is seldom emaciated. There is often slight oedema of the lower eyelids and of the feet, but these symptoms are generally late in appearing. The intellect is usually unimpaired, but answers to questions are slow, apathetic, and delivered in a low tone of voice, sometimes interrupted by long-drawn sighs. Sleep is occasionally, but not usually, heavy, insomnia being a more constant symptom. The tongue is pale, smooth, and dry; the breath offensive, with a cadaveric odour in severe cases. Stomatitis and bleeding gums are sometimes met with. In many cases dyspepsia, flatulent eructations, vomiting, and a painful sinking feeling at the epigastrium are prominent symptoms. These gastric disturbances are attributed by certain authorities to irritation of the cerebral centres by anæmia, by others to atrophy of the gastric glands. The gastric juice in a number of cases has been found to be deficient in hydrochloric acid, and in some few cases this acid has been absent, thus accounting for slow and imperfect digestion, anorexia, and nausea. Some patients, however, eat well, even to excess. Constipation or diarrhoea may occur, but usually the stools are of normal colour. Dyspnoea is sometimes the first symptom complained of. The breathing is generally accelerated, and, in advanced cases, is deep and noisy. The laboured breathing increases with the diminution of hæmoglobin, but not so rapidly as other symptoms, and is often absent as long as the patient is at rest. The action of the heart is regular and frequent. Sometimes there is visible evidence of dilatation, the impulse being diffused, and the area of præcordial dullness increased laterally. Systolic murmurs are heard over the cardiac region, sometimes loudest at the base, sometimes at the apex. A venous *bruit* in the neck is generally present. The pulse ranges between 100 and 120, and is regular, compressible, not small, often jerky, and possibly dicrotic.

One of the most striking clinical features of pernicious anæmia is the supervention of *hæmorrhages*. Epistaxis, menorrhagia, sometimes cerebral hæmorrhage, and towards the close of life petechial hæmorrhages and purpuric eruptions, may occur; but by far the most important are retinal hæmorrhages, because they serve as a diagnostic symptom of great value. The condition of the optic disc is

shown in the accompanying figure (fig. 1). For purposes of comparison reference should also be made to the coloured plates in the article on Ophthalmoscopy in Medicine. The fundus is pale, the arteries are narrow, the veins broad; the hæmorrhages are generally multiple, and flame-shaped, from their situation in the layer of nerve-fibres. They appear as linear striæ, rounded spots or

FIG. 1.—Retinal hæmorrhage. After QUINCKE.

patches, clustered around the optic disc, and may have whitish or yellowish centres, due in part to leucocytes, in part to degeneration. These hæmorrhages may be quickly absorbed, often lasting only a few weeks. There may be no disturbance of vision, unless the hæmorrhages are situated in the maculæ luteæ. In all the six cases observed by the writer retinal hæmorrhages were present.

Pyrexia is the rule in pernicious anæmia. It may be continuous for months, the evening temperature reaching 100° – 101° F.; or it may be intermittent with sudden exacerbations. The pyrexia as a rule is not severe, but occasionally the temperature may rise to 105° or 106° F. On the other hand, it may fall even as much as 10° below normal previous to death. Possibly the intermittent pyrexia may have some relationship to the toxæmia which causes the hæmolytic process.

The urine may be normal in quantity, except at the close of life, when it is often considerably diminished. It seldom contains albumen and never sugar. It is often of a deep colour, containing excess of urobilin, and there may be a direct association between the depth of colour and the hæmolytic process. In other instances, however, it is quite pale. The amount of nitrogen excreted *per diem* may be less than normal; but, as a rule, it is more than can be accounted for by the nitrogenous ingesta. Consequently it must be derived from the excessive waste of blood and tissue; but an incomplete oxidation of the nitrogenous substances leads to an excretion of urea and a deposition of fat. Uric acid often occurs in considerable quantities; indican, pathological urobilin, and pentamethylene-diamine have also been found in the urine, suggesting a morbid process in the gastro-intestinal tract. Free iron has been discovered in the urine by William Hunter.

Blood.—The blood in pernicious anæmia presents no changes absolutely characteristic of the disease. When drawn, it appears pale and watery, and the specific gravity is often greatly reduced. Examined microscopically, it invariably shows a considerable diminution in the number of red corpuscles, which may be reduced to 500,000 per c.mm.— $\frac{1}{10}$ of the normal—or even less in the last stages of the disease, the lowest estimation on record being 143,000 (Quincke). Generally there is a striking variation in the form and size of many of the red corpuscles (*see* BLOOD, Morbid Conditions of—coloured plate). It will be seen that some are much larger than normal (macrocytes); many, again, are pear-shaped or have an irregular contour (poikilocytes); and, finally, there are to be seen numbers of small, imperfectly developed corpuscles (microcytes). In a stained film-preparation numbers of nucleated red corpuscles are usually found, and sometimes eosinophilous cells. The corpuscles are usually of good colour. There is no leucæmia, but granular masses are common. Hayem holds that the presence of nucleated red corpuscles is a grave omen. There is a great diminution of hæmoglobin in the blood—sometimes in proportion to the falling off in numbers of the corpuscles; but, owing to many of the corpuscles being more highly charged with colouring matter than normal, the hæmoglobin-value of the blood may be excessive in relation to the number of the corpuscles. *See* BLOOD, Morbid Conditions of.

The spleen and liver are in some cases enlarged, especially the former. There is also evidence of affection of another important structure connected with the elaboration of the blood—namely, the bones. These may be tender, and the sternum is especially liable to be so affected.

NERVOUS SYMPTOMS.—Lichtheim was the first to call attention to a combined degeneration of the posterior and lateral columns of the spinal cord, in cases of profound anæmia. Some of the cases in which this degeneration has been found are rather cases of associated grave anæmia than of true pernicious anæmia. It is possible that a toxæmia which causes the hæmolytic process may also cause the degeneration of the tracts of nerve-fibres of the spinal cord. Such degeneration cannot be produced by experimental anæmia in animals; and although the anæmia would undoubtedly tend to accelerate a degenerative process, the evidence rather points to a toxin as the essential cause. The symptoms are mostly related to disorders of motility, viz. ataxia and paraplegia (*see* COMBINED DEGENERATION OF THE SPINAL CORD). The anæmia may however be assigned as the cause of various functional nervous disturbances, viz. irritability, loss of memory, insomnia, and in severe cases delirium and other mental disturbances, and convulsions and coma which sometimes precede the fatal termination. Monoplegia, hemiplegia, and other symptoms indicating destructive lesions of the brain may occasionally arise from cerebral hæmorrhage.

COURSE, DURATION, TERMINATIONS, AND PROGNOSIS.—Of 110 cases collected by Sidney Coupland, the total duration of the symptoms in 52 was from 1 to 6 months; in 24 from 6 to 12 months; in 25 from 1 to 2 years; in the remaining 12 cases they lasted for periods of over 2 years. Of 130 cases of primary idiopathic anæmia collected by Pye-Smith, 30 are said to have recovered. Death is usually the result simply of anæmia, and

special complications are exceptional. The prostration and weakness increase; the headache, vertigo, and vomiting become more distressing; the breathing becomes hurried, laboured, and deep ('air-hunger'); the cardiac palpitation is more marked; and the patient usually falls into a drowsy, lethargic state, either lying impassive, or tossing about in restless delirium. Occasionally he remains conscious to the last, unable to sleep, and feeling utterly miserable and dejected in consequence of the distressing headache and vomiting. Death may occasionally occur suddenly from syncope.

Some authors dispute the possibility of true pernicious anæmia being cured, and urge that those cases which recover cannot be considered 'pernicious.' The prognosis is always grave, if not absolutely bad; and even when a patient improves under treatment, and the condition of the blood would give hopes of a cure, a guarded opinion should always be given; for a fresh exacerbation of pyrexia, with hæmolysis, and a return of the symptoms in an aggravated form, generally occur without any apparent cause.

PATHOLOGY.—The examination of the blood and urine during life, taken in conjunction with the changes found in certain organs after death, has thrown some light upon the disease. In health a constant equilibrium is maintained between hæmogenesis and hæmolysis. The pigment of the urine (urobilin) and the pigment of the fæces (stercobilin) are both iron-free derivatives of hæmoglobin. The daily loss of these iron-free derivatives of hæmoglobin affords evidence of a constant and fairly uniform destruction of red blood-corpuscles which is continually being balanced by a corresponding hæmogenesis. The new corpuscles are formed probably in the marrow of bone, although some authorities consider that the blood-platelets may be their antecedents. Experiments on animals in which anæmia has been produced by successive blood-lettings have shown that the marrow of bone here takes on an abnormal functional activity, and that nucleated corpuscles, which are a characteristic of pernicious anæmia, may appear in the circulating blood. There are many reasons for believing that pernicious anæmia is due not to a failure in hæmogenesis but to excessive hæmolysis caused by the absorption from the alimentary canal of a toxine which induces a destruction of the blood in the portal circulation. Quincke first showed that in the spleen and kidneys and especially in the liver an iron-derivative of hæmoglobin (hæmosiderin) existed in so great abundance as to constitute a post-mortem characteristic of the disease. It can be readily demonstrated by placing slices of the organ in a solution of ammonium sulphide which turns it coal black, or better still by placing them in a solution of ferrocyanide of potassium acidulated with hydrochloric acid. If thin sections be prepared in this way, it will be found that the blue particles are most numerous in the portal zone of the lobule. In one acute case, observed by the writer, the blood-corpuscles contained in the branches of the portal vein were in all stages of disintegration, and in the clot numbers of blue-stained granules could be seen, thus affording presumptive evidence that the hæmolytic process was due to the absorption from the alimentary canal of some agent which induced this chemical change in the hæmoglobin. The amount of free iron which can be obtained from a normal liver is comparatively small, but in

pernicious anæmia it is of considerable quantity. Thus from a liver weighing 1,240 grammes Vasey obtained for the writer 27 grammes of ferric oxide. Not only does the liver contain this free iron, but also the spleen and kidneys, though to a much less extent. There is thus evidence of the existence in these organs of iron which is not again utilised for the formation of hæmoglobin. By the side of this fact we must place another, namely the presence of excess of urobilin in the urine, as further evidence of increased destruction of the red corpuscles. Along with this hæmolytic there may be found in a great number of the cases evidence of an increased hæmogenesis in the fact that there is an increase of red marrow and often a conversion of the yellow marrow into red. This myelogenic change in some cases is so marked that some authorities consider it to be a cause of the disease and not a result.

Now red corpuscles containing a due amount of hæmoglobin cannot be manufactured without iron; and although in pernicious anæmia the colour of the corpuscles may be even darker than normal, this does not show that they contain a sufficiency of iron. Since there is a large amount of iron lying useless in the liver, it might be suggested that this organ has a ferrogenic function (Delépine) which is disarranged, so that the iron cannot be re-utilised and that consequently although the disease may be primarily hæmolytic yet there is a disturbance of the hæmogenic function, progressive in character. Not only, however, do the corpuscles diminish in number, but the specific gravity of the blood is often much lower than normal. The evidence seems to support the view that there is absorbed from the alimentary canal some poison which causes chemical change in the blood of the portal system. The fact that in many cases the hydrochloric acid is diminished or even absent from the gastric juice would support the view of a change in the mucous membrane, possibly due, as Hunter suggests, to an infective catarrh, especially when gastric disturbances form so prominent a feature of the disease. The absence of the hydrochloric acid, however, alone could not cause pernicious anæmia, for in cancer of the stomach, in which this acid is usually absent, we do not have the clinical and

possible that the normal vital resistance to the absorption of poisonous substances engendered by fermentative processes occurring therein might be in abeyance, and poisons could be absorbed which would lead to an altered condition of the portal blood, disintegration of the corpuscles and deposition of iron in the liver, with excess of the iron-free derivative of the hæmoglobin (urobilin) in the urine. The fever which often shows exacerbations coincident with evidence of increased hæmolytic suggests a toxæmia; the fact that a few successful cures have been reported (Gibson) by antiseptics such as β -naphthol suggests the plausibility of this hypothesis. The writer's experience does not support the view that the anæmia is due to hæmorrhages. Some authors include in pernicious anæmia cases of grave and fatal anæmia due to definite causes, such as *Ankylostoma duodenale*; it may however be remarked that in connection with the anæmia caused by this parasite there is no great excess of free iron in the liver. The evidence in favour of a specific bacterial cause is still very incomplete.

Although no *specific* organisms have been found in the blood or organs in this disease, yet many of the symptoms—viz. the gastro-intestinal disturbances, the peculiar cadaveric odour of the breath, the irregular attacks of pyrexia, and the presence of indican and other bodies in the urine—suggest the absorption by the portal circulation of some poison formed by the growth of micro-organisms. It has been shown that the blood in pernicious anæmia, as in many septic diseases, after being drawn allows hæmoglobin-crystals to form spontaneously. When arsenic is administered, the blood is said to lose this property, suggesting an explanation of the value of the drug in the treatment of the disease. Again, if putrid serum be added to healthy blood, crystals of hæmoglobin form. It is possible therefore that some intestinal poison sets up a hæmolytic process in the portal circulation, and that the hæmoglobin is broken up in the liver—into urobilin, which escapes by the urine, and free iron, which remains in the cells and capillaries of the portal zone. The urobilin, which passes from the hepatic veins into the general circulation, gives rise before its excretion to the lemon-yellow colour of the skin and fat (urobilin-jaundice).

DIAGNOSIS.—The principal diagnostic features of pernicious anæmia are the following: (1) the patient is usually *middle-aged*; and, except in the case of women, there is nothing to account for the onset of the disease; (2) the absence of any organic disease; (3) the severe and progressive anæmia; (4) the great diminution of the corpuscles and colouring matter of the blood; (5) alteration in the shape and size of the corpuscles and the presence of nucleated corpuscles; (6) signs of fatty degeneration of the heart, without arterial degeneration or valvular disease; (7) retinal hæmorrhages; (8) irregular and occasional pyrexia; (9) no emaciation, but frequently rather an excess of subcutaneous fat; (10) lemon-yellow coloured skin and high-coloured urine; (11) gastric disturbances; (12) carious teeth and stomatitis.

The diseases for which pernicious anæmia has been mistaken are Bright's disease, ulcerative endocarditis, tuberculosis, Addison's disease, cirrhosis of the liver, cancer of the stomach and malignant disease of other internal organs, chronic ulcer of the stomach, parasitic affections, such as ankylostomiasis and pseudo-leucæmia myelo-

FIG. 2.—Section of the liver showing a single lobule after treatment with ferrocyanide of potassium solution and hydrochloric acid. The dark shading indicates the deposit of iron in the portal zone. $\times 75$.

pathological phenomena of the disease, notwithstanding the associated anæmia (see BLOOD, Morbid Conditions of). But if the *infective* catarrh spread to the intestine, as suggested by Hunter, it is

genica. It occurs at an age when idiopathic anæmia or chlorosis is unlikely to be met with; moreover an examination of the blood should serve to differentiate it. See BLOOD, Examination of.

TREATMENT.—Preparations of iron are useless in pernicious anæmia, and occasionally even injurious. Most of the recorded cases of recovery have been treated with arsenic. Although it is not a specific, it generally prolongs life. Liquor arsenicalis should be given in 3-minim doses, rapidly increased to 10 minims, three times a day; and if it cannot be tolerated, on account of gastric disturbances, it may be administered subcutaneously. Hayem recommends in addition the inhalation of 15 litres of oxygen a quarter of an hour before each of the two principal meals; and after meals a one per cent. solution of hydrochloric acid. Ferratin and bone-marrow are also remedies which have been tried with varied success. A few most successful results have been obtained by the use of antiseptic drugs such as salol, β -naphthol, and bismuth salicylate. If, as seems probable, the toxine is generated in the alimentary canal by a fermentative process of microbial origin, and absorbed by the portal system, it is easy to understand that drugs which would arrest such a process might yield beneficial results. Irrigation of the intestine and *lavage* of the stomach have also been tried in some cases with apparent success. It is necessary to give a nutritious diet, very easy of digestion, such as milk, beef-tea, eggs, scraped raw beef, and meat-juice. It is sometimes necessary to limit the diet to peptonised or humanised milk, whey, and white of egg. If vomiting be very severe, nutrient enemata may be used. Transfusion has been tried in some cases, but it is doubtful whether it has ever done more than prolong life for a short time. Defibrinated human blood should be used, and not more than half a pint should be injected at once.

FREDERICK W. MOTT.

ANÆSTHESIA: Local.—**DESCRIPTION.**—To produce local anæsthesia or, more correctly, local analgesia, one of the salts of cocaine or its analogues is injected into the tissue about to be operated on. The detailed method now employed is based upon the observation of Corning that cocaine applied to a sensory nerve in its course abolishes sensation to pain throughout the tissues to which it is distributed. A sterilised watery solution of hydrochlorate of cocaine (1 to 2 per cent.) is injected by means of a fine hollow needle and syringe all over the area to be operated on. In the first place it is distributed along the line of first incision directly under the epidermis, i.e. in the papillary layer of the skin, in such a way as to produce a white wheal. Then by successive injections it is distributed layer by layer through the subjacent tissues, following as far as possible the distribution of the nerves. If done properly the tissues are rendered analgesic in about five minutes and can be incised and dissected without causing pain for about half an hour. This analgesia may be rendered more complete and rapid in the case of a hand, foot, finger, or toe, by previously checking the return of blood from the part by encircling the part on the central side with a piece of rubber-tubing.

There is, however, always some risk of the toxic effects of cocaine being developed. This has led to a search for some equally effective but less dan-

gerous anæsthetic, and such appears to have been found in an allied chemical substance, β -Eucaine hydrochloride, which seems to be less toxic than cocaine in the proportion of one to five. This is now used in the following solution: β -eucaine 1 part, sodium chloride 8 parts, water 1000 parts. The addition of eight parts of common salt per thousand of water neutralises the osmotic effects of the latter, and thus eliminates one element in the production of pain. Such a solution may be used in almost any amount required in the manner above described, as much as 10½ oz. having been employed in a single operation without any ill effect. To avoid causing pain the solution must be used at body-heat and injected slowly. A syringe, sterilised by boiling, and having a capacity of 10 c.c., is the best instrument to employ. The most convenient method for making the solution is to have powders made up in papers containing enough β -eucaine and pure sodium chloride to make 7 oz. of solution. This amount of boiling water is placed together with one of the powders in a beaker and boiled for a few minutes. The vessel is then covered to keep out impurities and placed in a basin of cold water until cooled to blood-heat, after which it is kept in a warm water-bath to maintain the desired temperature.

No toxic effects result from the use of β -eucaine employed in this way. But there are certain disadvantages from the operator's point of view. It is difficult for him to divest his mind of the impression that the patient, who is perfectly conscious, is also sensible of pain, especially as the sense of touch is not abolished. He is therefore inclined to operate more slowly and deliberately. Indeed this is necessary: for it must be remembered that any dragging on tissues may affect structures outside the zone of analgesia and so produce pain. For instance, in the case of a radical operation for the cure of inguinal hernia, though the first incision and dissection may be quite painless, any dragging on the cord will be felt acutely, as the proximal part of this structure cannot be reached by the injection. Bearing this fact in mind, however, we may avoid the evil by careful manipulation, though with some expenditure of time. The artificial oedema produced by the injection is of little moment in most operations, but would be dangerous about the mouth or fauces, and the method should never be used there.

The chief advantages of the method are the avoidance of the risks, immediate and remote, of general anæsthesia. Moreover, the patient is not denied food before or after the operation. There is usually no vomiting, and this in itself eliminates much distress and some risk, especially in abdominal operations. The method is seen at its best in such cases as strangulated hernia in old people who are much run down, or where colotomy has to be performed. These patients are proverbially bad subjects for chloroform or ether, and suffer much in many cases from subsequent vomiting. Again in the excision of thyroid-tumours the method answers admirably. The writer during the last few years has employed the method in numerous other operations, such as those for the radical cure of hernia, for empyemata, for intestinal anastomosis, and for the removal of small tumours.

The method has recently been extended in a very remarkable way. Professor Bier caused some cocaine solution to be injected into his own lumbar spinal cord and into that of a friend. The result was com-

plete analgesia of both lower extremities. As a result of these experiments amputations of the legs have been performed under similar conditions, and, according to the published accounts, absolutely without pain. The cases, however, are not numerous, and are insufficient to enable surgeons to decide as to the practical utility of the method.

ARTHUR E. BARKER.

ANÆSTHETICS, GENERAL.—DEFINITION. General anæsthetics may be defined as drugs capable of temporarily inducing *general surgical anæsthesia*, i.e. a loss of consciousness and sensibility throughout the entire organism.

METHODS OF PRODUCING ANÆSTHESIA.—The anæsthetics commonly employed are nitrous oxide, ether, chloroform, and the A.C.E. Mixture.

Nitrous oxide is usually supplied, in liquefied form, in suitable cylinders. Fifteen ounces of the liquefied anæsthetic will furnish about fifty gallons of gas. Nitrous oxide may be inhaled (1) in its pure state; (2) it may be given mixed with air, either by letting the patient take an occasional breath of air, or by allowing the admixture of a definite percentage of air (10 to 20 per cent. according to the type of patient) with the anæsthetic gas before it is inhaled; or (3) it may be administered mixed with oxygen (5 to 9 per cent.), a regulating stopcock being employed. Two cylinders should be coupled together in case one is emptied during the administration. The average quantity of nitrous oxide required to anæsthetise patients for dental operations is five or six gallons, but if breathing 'to and fro' into the bag be permitted towards the end of the administration, a smaller quantity will suffice.

Ether prepared from rectified spirit is preferable to that obtained from methylated spirit, although the latter variety may pass the Pharmacopœial tests. Great care is necessary in using ether in the proximity of a naked flame, as the vapour is highly inflammable. There are two systems of etherisation, which may be termed the *semi-open* and the *close* respectively. In the first or *semi-open* system a felt cone or Rendle's mask is used; ether is poured upon the sponge within the cone or mask, and all expirations escape in the air. The second or *close* system involves the employment of a bag-inhaler, and there are two methods for applying this system, viz. Clover's and Ormsby's.

Chloroform should be obtained in small bottles, which should be kept in a cool dark place. The author has been unable to detect any clinical differences between Duncan and Flockhart's chloroform prepared from rectified spirit and the chloroform of the same firm prepared from methylated spirit. There is only one system at present known of employing chloroform, viz. the *open* system, without re-breathing; but there are several methods of applying this system. Of these two may be mentioned—Skinner's and Jünker's. Skinner's mask, upon which chloroform is sprinkled from a drop-bottle, has advantages over lint, handkerchief, or towel, in that it is more manageable, and the chloroform is less likely to injure the skin. Jünker's inhaler is principally of use when only analgesia is required, as in normal labour, and for maintaining anæsthesia during operations about the upper air-passages. It is a mistake to suppose that Jünker's inhaler necessarily robs chloroform of its dangers. For general use a Skinner's frame is preferable to any other appliance.

The A.C.E. mixture, which consists by volume of alcohol 1 part, chloroform 2 parts, and ether 3 parts—the last two constituents being made from rectified spirit—is useful in many cases. Equally good results are obtainable without alcohol. The mixture is best administered by means of a Skinner's mask, followed by a Rendle's mask, but in the case of infants the former will suffice.

It is advisable in many cases to use first one anæsthetic and afterwards to change to another. The following '*successions of anæsthetics*' are valuable: (1) the nitrous oxide—ether sequence; (2) the A.C.E.—ether sequence; and (3) the ether—chloroform sequence. The best method of administering 'Gas and Ether' is to adapt a partly full gas-bag to a Clover's portable ether-inhaler. Clover's combined gas and ether apparatus is too cumbersome and complicated to be recommended. The great advantage of this sequence is that unconsciousness is rapidly induced without discomfort, and without struggling or excitement. The second of the sequences mentioned is valuable when nitrous oxide cannot be obtained. Anæsthesia is induced by the A.C.E. mixture, and at the commencement of rigidity the Rendle's inhaler is changed for an Ormsby's apparatus charged with ether. The third of the sequences mentioned is one which is often called for in consequence of difficulties experienced in etherisation. While it is an exceedingly valuable one, considerable care and experience are needed in changing from ether to chloroform. As a general rule, patients should evince distinct signs of approaching recovery from ether-anæsthesia before chloroform is applied, and under no circumstances should a change be effected during violent struggling.

PREPARATIONS AND PRECAUTIONS.—However simple the case may appear to be, it must never be forgotten that the administration of an anæsthetic is a responsible task. Indeed, as a general rule, difficulties are more likely to arise in perfectly healthy patients, about to undergo or undergoing trivial operations, than in cases which are apparently more serious. Anæsthetics should never be administered by unqualified persons. It is necessary to have had considerable experience before even moderate success can be achieved, and lives are undoubtedly often sacrificed owing to the administration of anæsthetics being placed in incompetent hands. There are certain preparations and precautions to be adopted on all occasions. (1) The anæsthetist should have at hand a Mason's gag, tongue-forceps, an efficient form of mouth-opener, instruments for tracheotomy, two or three pieces of sponge, a small mouth-prop, a towel and a small basin. (2) All constricting clothing should be unfastened, artificial teeth removed, and loose teeth carefully noted. (3) With regard to diet, an interval of five hours between the last meal and the administration is generally advisable. For operations before 10 A.M. nothing whatever should be given after the evening meal of the preceding day. For midday operations a light breakfast of tea and toast five hours before may be permitted. In the case of very feeble subjects an enema of beef-tea and brandy an hour before the operation is advantageous. (4) An aperient should be given the night next but one before the operation, and an enema on the morning of the operation. (5) The best posture for the administration is the supine, the head, but not the shoulders, being slightly raised and turned to one side. In

cases of intestinal obstruction, or in others in which vomiting has been taking place, the patient should be anæsthetised with one shoulder raised by a pillow, and the head turned well to the opposite side. Whatever posture be adopted, the head should be neither flexed nor extended upon the trunk. The semi-recumbent posture should be avoided, and the same may be said of a special posture, which is erroneously regarded as suitable for operations upon the throat, viz. that in which the head is extended over the end of the table. Patients should be instructed to breathe through the mouth, rather than through the nose. (6) The chest should always be examined before selecting the anæsthetic.

CHOICE OF ANÆSTHETICS.—Whenever practicable, nitrous oxide should be employed, either with oxygen, with air, or alone, since it is the safest known anæsthetic. If inadmissible or unobtainable, ether should be chosen. In other words, nitrous oxide and ether should be the two routine anæsthetics for general surgical work, the A.C.E. mixture and chloroform being reserved for special cases and for special operations.

THE PATIENT.—As a rule women are more easily anæsthetised than men. Infants and senile subjects usually take anæsthetics well, the A.C.E. mixture producing good results. Men of powerful build with thick necks must be anæsthetised with care. Feebly developed subjects usually pass into anæsthesia without trouble. Vigorous, full-blooded, alcoholic patients, and very nervous subjects usually require considerable quantities of the anæsthetic, and the excessive use of tobacco may give rise to difficulties. Patients suffering from any respiratory difficulty, as well as those in whom respiration is particularly prone to become embarrassed under the anæsthetic, must be treated with caution. The worst subjects for anæsthetics are (1) obese patients suffering from acute intestinal obstruction, with vomiting and abdominal distension; (2) cases of emphysema with much dyspnoea; (3) patients with dyspnoea from tracheal pressure, especially if the obstructed breathing be associated with bronchial secretion or pulmonary oedema; and (4) fat, flabby, alcoholic men suffering from some exhausting disease. Special care is needed in anæsthetising patients with nasal obstruction or enlarged tonsils. In many of such cases, a small mouth-prop should be inserted between the teeth. Those who are subject to dyspnoea should be permitted to lie in the position most comfortable to them: when anæsthetised they can be cautiously moved. Generally speaking, the presence of even moderate dyspnoea calls for chloroform; but patients with chronic bronchitis, emphysema, and chronic lung-affections may usually be successfully anæsthetised by the A.C.E. mixture. The subjects of *morbus cordis* usually take anæsthetics well, provided that no asphyxial strain be thrown upon respiration or circulation. As a general rule, the A.C.E. mixture gives the best results in cases of advanced heart disease. 'Close' etherisation should be avoided in this class of patients. Should there be a history of antecedent cerebral hæmorrhage, ether is contra-indicated.

THE OPERATION OR CONDITION REQUIRING ANÆSTHESIA.—Short operations within or about the *mouth, nose, and nasopharynx* may be performed under nitrous oxide or ether. The available period of anæsthesia after a dose of pure nitrous oxide is thirty seconds; after a full administration of nitrous

oxide and oxygen, forty-four seconds; after three or four minutes' etherisation, about ninety to one hundred and twenty seconds. By administering ether for ten or twelve minutes an anæsthesia of about four or five minutes may be secured. Tooth-extraction, the removal of nasal polypi, tonsils, and adenoid growths, and numerous other short operations may thus be performed. When a longer anæsthesia is desired, it is usually best to maintain it by means of chloroform, employing a Jünker's inhaler for the purpose, the tube of which is passed into the nose or mouth. A large experience is needed to decide what particular degree of anæsthesia should be maintained. The best posture for cases of this group is, undoubtedly, the lateral. In this posture the tongue may be removed, the antrum opened up, and numerous other operations performed without the slightest embarrassment to breathing. When the actual cautery is to be used, the patient must be under chloroform, as ether-vapour is inflammable. Should the purely dorsal or the sitting posture be employed, careful and repeated swabbing with coarse sponges, unattached to holders, will be needed. Speaking generally it is advisable to retain the swallowing and coughing reflexes in these cases. In intra-laryngeal operations (for which chloroform is needed) these reflexes must be abolished. For operations about the *neck*, and particularly in thyrotomy, tracheotomy, and thyroidectomy, chloroform should be used.

In *abdominal surgery* very deep anæsthesia is needed, and, unless the administrator has had a large experience with chloroform, he should employ ether, with which anæsthetic the margin of safety is sufficiently large to allow of its being freely pushed. It is not always safe to abolish all traces of reflex abdominal rigidity, although this can be done in most cases. In very prolonged operations, chloroform, or some mixture containing it, should be used in preference to ether. There is often considerable shock in these cases, especially during manipulations in the region of the solar plexus.

In operations upon the *pleura or lung* it is generally taught that chloroform or the A.C.E. mixture should be given; and this course may be followed in most cases. But, in the worst subjects, ether (administered by the semi-open system) is to be recommended, since, if respiration become suspended even for a short time while chloroform is being used, fatal syncope may rapidly follow.

In operations upon the *genito-urinary organs and rectum* very deep anæsthesia is needed: and ether is preferable to other anæsthetics. Operations upon the *kidney* are often attended by considerable shock. The same remark applies to operations upon the *breast*. In *cerebral surgery* chloroform is generally indicated.

When anæsthetics are required for their analgesic effects, as in *normal labour* and *biliary colic*, chloroform may be advantageously chosen. When profound muscular relaxation is needed, as in reducing dislocations, very deep ether-anæsthesia is safer than a corresponding state of chloroform-narcosis. Muscular relaxation cannot be depended upon under nitrous oxide, even when administered with oxygen.

PHENOMENA OF ANÆSTHESIA.—(a) *Nitrous oxide*. The phenomena will depend primarily upon the system of administration adopted. When the pure gas is administered through accurately working valves, and when each expiration escapes, the

following phenomena appear:—respiration becomes deeper and quicker; the pulse smaller and more frequent, and the colour of the face increasingly dusky. The pupils dilate; deep guttural stertor becomes audible; and clonic muscular twitchings of an epileptiform character make their appearance. The average inhalation-period is about one minute, and it is mechanically impossible to administer the gas after deep stertor has set in. The average available period of anæsthesia after removing the face-piece is thirty seconds. The lividity, stertor, and jactitation may all be lessened or completely removed by administering oxygen with nitrous oxide. For this purpose a regulating stopcock is necessary, and, after starting with 2 or 3 per cent. of oxygen, the percentage may be increased to 8, 9, 10, or even 20 per cent., according to the type of subject. In the best forms of anæsthesia thus induced, the breathing is sleep-like or softly snoring, and the pulse slightly accelerated; there is little or no change of colour; and clonic movements are completely absent. The effects produced by nitrous oxide and air are more satisfactory than those obtainable by the pure gas, but less satisfactory than those produced by nitrous oxide and oxygen. Careful preparation as to diet is necessary in using the last-named mixture, as there is undoubtedly a greater tendency to vomiting during and after its use than in the case of nitrous oxide given alone or administered with occasional breaths of air. Stertor and 'jactitation'—one or both—are the signs that pure nitrous oxide has been administered to its full extent; and when either or both occur, fresh air must be admitted. Caution is needed in pushing the administration to its full extent in short-necked subjects, in patients with affections of the throat or nose, in very young children, in persons with any marked dyspnoea, and in senile subjects. The signs of non-asphyxial anæsthesia are softly snoring breathing, and an insensitive conjunctiva.

(b) *Ether*.—This anæsthetic is usually given by Clover's Portable Regulating Inhaler, which, in cold weather, and when about to be used for anæsthetising powerfully built subjects, should be very slightly warmed. The figures on the inhaler indicate the extent to which the to-and-fro air-current is made to pass over ether, and not the relative proportions of ether and air. When properly used, anæsthesia can be secured in about three and a half minutes without excitement or struggling.

The following method of administration should be adopted:—1. The patient's head should be turned well to one side. 2. He should be instructed to breathe freely through the *mouth*. 3. The inhaler, charged with ether, and with the indicator at 'o,' should be applied so as to catch sufficient expired air to fill the bag. 4. To-and-fro breathing, with the indicator at 'o,' should be permitted for half a minute. 5. The ether reservoir should then be rotated continuously but almost imperceptibly, '1' being reached at the end of the first minute, '2' at the end of the second minute, and '3' at the end of the third minute. 6. One breath of fresh air should be admitted when stertor begins. 7. After this breath of air has been given, the patient's colour, rate and depth of breathing, and general condition, will indicate the extent to which further supplies of fresh air may be allowed. When once the cornea has become in-

sensitive to touch, the inhaler should be removed and fresh air admitted at frequent intervals. No definite rule applying to every case can be formulated; but the weaker the patient and the longer the administration, the greater should be the quantity of air allowed. Should excitement and struggling occur, the administration must be continued. In very exhausted subjects but little ether will be needed, and the air-supply must be ample. The signs of anæsthesia are:—Regular snoring breathing; very slight duskiness, disappearing when plenty of air is allowed; moderate dilatation of the pupil; general muscular flaccidity; a quick, full pulse; and an increased secretion of mucus and saliva. When ether is given by the semi-open system, excitement and struggling generally occur, large quantities of the anæsthetic are needed, and several minutes elapse before surgical anæsthesia takes place.

c. *Chloroform*.—It is a mistake to administer this anæsthetic either too sparingly or too recklessly. In the former case, prolonged emotional disturbances, lividity, pallor, vomiting, and feebleness of pulse will be produced, while anæsthesia will be delayed; and syncope may even be initiated. In the latter case, 'holding the breath,' coughing, struggling, and asphyxial complications may ensue. It is also important to remember that with concentrated vapours a dangerous or fatal dose of chloroform may easily be inhaled. A very weak vapour should be used at the outset, and a continuous atmosphere of a *moderately strong* vapour kept up till anæsthesia begins to appear. Should excitement and struggling arise, frequent breaths of fresh air must be permitted. By degrees the hampered breathing of the excitement-stage will subside, and regular softly snoring respiration will become audible; the muscles will relax, the pulse will become somewhat slower than the normal; the face less florid; the corneæ insensitive to touch; and the pupils moderately contracted. An attempt should be made to maintain this condition, taking as guides (1) the corneal reflex, (2) the respiration, (3) swallowing movements, (4) the pupil, (5) the state of the muscular system, (6) the colour of the face, and, when working without a trace of corneal reflex, (7) the pulse. In many patients it is possible to retain a very slight corneal reflex; in such cases, provided respiration be free and there be no indications of shock, the pulse may be disregarded. The pulse is, however, of great value as a guide in profound anæsthesia, for it will become slower and smaller with more chloroform, and quicker and fuller with less. Provided the patient be properly anæsthetised, the breathing will become quieter with less chloroform, and deeper with more; but in too profound an anæsthesia more of the anæsthetic will induce a quiet form of breathing from incipient bulbar paralysis.

As compared with ether anæsthesia, that of chloroform is less satisfactory so far as respiration and circulation are concerned. But by carefully watching the above signs it is possible to administer chloroform safely. The utmost vigilance, however, is necessary in conducting the administration in cases requiring the profound effect of the drug.

d. *A.C.E. Mixture*.—The effects of this are almost identical with those of chloroform, except that the pulse and breathing are of a more satisfactory type.

THE DIFFICULTIES, ACCIDENTS, AND DANGERS CONNECTED WITH ANÆSTHESIA.—Much miscon-

ception prevails with regard to the nature and mode of origin of the various difficulties which may arise in connection with surgical anæsthesia. It is probably not an exaggeration to say that in five out of six cases in which dangerous symptoms arise, such symptoms are not directly dependent upon an overdose of the anæsthetic. There is a remarkable tendency under all anæsthetics for respiration to become embarrassed, and this tendency is, if anything, more marked during light anæsthesia, when the muscular system is not relaxed, than during surgical narcosis. Again, it by no means follows, because a patient is exceedingly weak or is the subject of cardiac disease, that there will be an unusually great liability to dangerous symptoms. The strongest and most vigorous patients often give the greatest trouble to the anæsthetist.

(a) *Primary respiratory failure.*—Respiration may be interfered with in one of three ways:—(1) from occlusion of the upper air-passages, (2) from conditions affecting the bronchi, pleuræ, or thoracic parietes, or (3) from paralysis of the nervous mechanism of respiration. The symptoms presented by the patient will depend upon the anæsthetic employed, the degree of anæsthesia at the time of the arrested breathing, and the cause of the arrest.

(1) Occlusion may take place at various points. The teeth may become clenched; the tongue engorged and swollen; and the nasal air-way shut off by the soft palate. This state is not uncommon in certain subjects during incipient anæsthesia. Or the tongue may be spasmodically drawn backward in the course of stertor, till the glottis is completely covered. 'Falling back of the tongue,' in its literal sense, is rare, only occurring in certain positions of the head, and in complete muscular relaxation. Partially performed deglutition will necessarily arrest breathing, and is, perhaps, the most common cause of temporary suspension of the respiratory functions. Laryngeal spasm is also a common cause of obstruction. It may be of reflex origin, i.e. due to the operation, or it may depend upon local irritation caused by the anæsthetic vapour, or by mucus or blood. There is also a paralytic state of the superior aperture of the larynx which may induce obstruction. Again, foreign bodies, including blood, mucus, pus, and vomited matters, may obstruct breathing. Lastly, there are various pathological conditions of the naso-pharynx which may cause obstruction during anæsthesia, either from alteration in position of parts, or from increase in size owing to venous engorgement. Whatever the nature of the occlusion may be, the effects produced upon the patient will be the same, viz. the appearance of asphyxial symptoms. If the anæsthesia at the time be light and the circulation good, increasing duskiness will occur, abortive attempts at breathing as evidenced by thoracic and abdominal movements will continue for a time, the pulse will gradually fail, and pallor may replace cyanosis. A vigorous man who becomes asphyxiated owing to obstructive stertor under nitrous oxide may retain a pulse at the wrist for several minutes; whereas a flabby and obese subject with a dilated heart, who is being anæsthetised by chloroform, may lose his pulse almost immediately if the slightest embarrassment to breathing take place. Such a case may easily be mistaken for one of primary cardiac failure. The treatment in all cases should be to remove the slightest embarrassment to breathing immediately it is detected. The lower jaw should

be pressed forwards; the head slightly extended; the mouth opened by a Mason's gag; the tongue-forceps applied; any foreign body removed; and forcible compression of the chest employed. Blood, mucus, &c., must be removed by sponging, attention being paid to posture. Should the larynx have been invaded by these fluids, forcible compression of the chest, with sponging, will usually suffice to restore breathing. Forcible traction of the tongue will usually relieve laryngeal spasm. If these measures fail, artificial respiration should be attempted with the hope of overcoming the obstruction, and if this be fruitless tracheotomy must be performed. (2) Little need be said with regard to cessation of breathing dependent upon conditions affecting the bronchi, lungs, pleuræ, and thoracic parietes, for in such cases some pathological condition is generally present. Spasm of the respiratory muscles, which is occasionally met with during the stage of struggling and excitement, is, however, a serious complication. It usually passes off spontaneously, but occasionally resists all treatment. Artificial respiration, forcible inflation of the lungs, and venesection constitute the treatment mostly likely to succeed. (3) With regard to paralytic cessation of breathing, this takes place as the immediate result of a toxic dose of the anæsthetic. There is no obstruction; there is no spasm; but breathing fails, sometimes gradually, sometimes abruptly. The treatment is immediate artificial respiration. The mouth should be opened, the tongue pulled forwards, and Sylvester's method of artificial respiration applied. See ARTIFICIAL RESPIRATION and RESUSCITATION.

(b) *Primary circulatory failure.*—It occasionally happens that the pulse ceases at the wrist while respiration is proceeding regularly. This condition may arise under all anæsthetics, and, while it undoubtedly calls for careful attention, and in many cases treatment, it by no means implies imminent danger. By far the most common cause of the condition is the surgical procedure itself. Surgical shock may occur in all stages of anæsthesia. It may be characterised by slight evidences of cardiac inhibition—the pulse becoming slow, feeble, or irregular—or it may be so marked as apparently to threaten the life of the patient. It is questionable, however, whether surgical shock, occurring independently of hæmorrhage, is ever actually fatal. It is most common in renal, abdominal, mammary, and cervical operations. It may take the form either of cardiac inhibition or of vaso-motor paralysis, leading to an accumulation of blood in the venous system. In minor cases of surgical shock the lips and cheeks should be briskly rubbed with a cloth, and somewhat less anæsthetic given. In more grave cases the anæsthetic should be withheld, the head lowered, the legs raised, strychnine injected, and an enema of hot brandy and water administered. In the worst cases intra-venous saline injections should be given, and posture and freedom of respiration carefully studied. When chloroform is administered in toxic doses the pulse may cease before respiration, even in the healthiest subjects, but with ether this never occurs, save in patients in a very feeble condition. Primary circulatory failure has also been met with by the writer under nitrous oxide in a patient with aortic disease. Impending vomiting is sometimes associated with feeble or absent pulse. The treatment for primary circulatory failure produced by the anæsthetic and not by the operation is artificial respiration. The

very grave error has often been committed of treating this condition by drugs and stimulants. Experience shows these latter remedies to be absolutely useless. Indeed they are actually dangerous because they may stand in the way of prompt and efficient blood-aëration. Attention to posture is important, and when any symptoms of syncope arise, partial or complete inversion may be advantageously adopted in combination with artificial respiration. By way of summary it may be said that, putting aside surgical and pathological causes of difficulties, reliance must be placed upon artificial respiration and posture, and that any other measures should be regarded as of secondary importance.

AFTER-EFFECTS OF ANÆSTHETICS.—The after-effects of anæsthetics depend upon the presence or absence of food within the stomach at the time of the operation, and upon the duration of the administration. There are of course other factors, such as the type of subject, the quantity of anæsthetic used, and the kind of anæsthetic. The after-effects of nitrous oxide are very slight, provided care be taken in regulating the diet. Vomiting after ether is more common than after chloroform, although protracted vomiting is more often met with under the latter anæsthetic. In the experience of the writer the best results, so far as the absence of after-effects is concerned, are to be obtained by the gas-ether-chloroform sequence, the first two anæsthetics being used for inducing anæsthesia, and chloroform for maintaining it. By keeping the head turned upon one side, so as to allow the escape of mucus, and by maintaining an equable anæsthesia, after-effects are less likely to occur than under other circumstances. As a general rule no nourishment should be given till the patient feels inclined to take it. After short administrations a little tea or coffee is often much appreciated. After long administrations clear soup, beef-tea, or solid meat-essence may be given. Milk and eggs must be avoided. In cases of much nausea or vomiting two-ounce doses of very hot water may be taken. Inhalations of vinegar are also recommended. In very severe cases a blister may be applied to the epigastrium. It is important that directly the administration is suspended the patient should be placed upon his side, in order that mucus or vomited matters may pass freely from the pharynx and mouth; and he should be left undisturbed in a quiet and darkened room. Jolting and other movement of the bed should be, if possible, avoided. The room should be well ventilated, but care should be taken not to subject the patient to draughts.

F. W. HEWITT.

ANAKHRE.—**SYNON.** : *Goundou*; *Henpuye*. *Fr. Gros nez.*—This singular deformity, the result apparently of a chronic osteoplastic process affecting the adjacent parts of the superior maxillæ and nasal bones, is not uncommon in the natives of certain parts of the West Coast of Africa, particularly on the Ivory and Gold Coasts and their respective *hinterlands*. It occurs, though rarely, among West Indian negroes. In well-marked examples oval, symmetrical, smooth, bony outgrowths form prominent swellings at the sides of the nose. In some instances the growths are so large that they interfere with the line of vision, the patient being obliged to lower the head in order to see over them. The integuments are not involved, nor is there any obstruction of the nasal ducts or of the nostrils.

The swellings consist of a thin cortex of dense bone enclosing a core of cancellous tissue. They commence—according to Chalmers—during or shortly after an attack of yaws—with nasal discharge and much headache. After a time the discharge and pain cease but the swellings continue to increase. Growth may be spontaneously arrested at any stage, or it may steadily progress till each mass attains the size of a goose's egg, producing a hideous deformity and perhaps completely occluding vision, although not destroying the eyes. Occasionally, though rarely, the disease is confined to one side of the face. It never ulcerates, breaks down, or spontaneously subsides.

Chalmers considers that anakhre is a sequel of yaws, the result of the interference with the nutrient vessels of the bones—a consequence of intra-nasal ulcers. Further evidence is however required before this view of its origin can be considered as established. It is difficult on such an hypothesis to account for the symmetry of the swellings and for the singularly limited geographical range of the disease. Macleod regards anakhre as parasitic; Strachan suggests that it may be a racial peculiarity: neither of these views can explain all the facts.

TREATMENT.—The swellings are easily removed by surgical means and do not recur.

PATRICK MANSON.

ANALGESIA (ἀ, priv.; and ἄλγος, pain).—Absence of sensibility to painful impressions. *See* SENSATION, Disorders of.

ANAPHRODISIA (ἀ, priv.; and Ἀφροδίτη, Venus).—Absence of sexual appetite. Sometimes used to express impotence. *See* IMPOTENCE.

ANAPHRODISIACS.—**DEFINITION.**—Medicines which diminish the sexual passion.

ENUMERATION.—The agents employed as anaphrodisiacs are:—Ice; Cold Baths—local and general; Bromide of Potassium; Bromide of Ammonium; Iodide of Potassium; Conium; Camphor; Digitalis; Purgatives; Nauseants; Circulatory Depressants; and Bleeding.

ACTION.—The erection which occurs in the genital organs during functional activity is due to dilatation of the arteries in the erectile tissues, and is regulated by a nervous centre situated in the lumbar portion of the spinal cord. From this centre vaso-inhibitory nerves pass to these arteries, and cause them to dilate whenever it is called into action. It may be excited reflexly by stimulation of the sensory nerves of the genital organs and adjoining parts, or by stimuli from the alimentary canal. It may also be excited by psychical stimuli passing to it from the brain. Some anaphrodisiacs may act by lessening the excitability of the nerves of the genital organs, as the continuous application of cold, and probably, also, bromide of potassium; some by diminishing the excitability of the genital centres in the spinal cord and brain, as bromide and iodide of potassium, and conium; others by influencing the circulation, as digitalis. There are also adjuvant measures, of a hygienic and moral character, which greatly assist and may even replace anaphrodisiac medicines, such as a meagre diet, especially of a vegetable nature, the avoidance of stimulants, and the pursuit of active mental and bodily exercise. Everything tending to stimulate the genital organs, or to increase the flow of blood to them or to the lumbar portion of the spinal cord, should be avoided, such

as warm and heavy clothing, or pads about the hips or loins; and a hard mattress should be used in place of a feather-bed. Everything likely to arouse the passions, such as certain novels, pictures, theatrical representations, &c., should also be shunned.

USES.—Anaphrodisiacs are employed to lessen the sexual passions when these are abnormally excited in satyriasis, nymphomania, and allied conditions. As such excitement may sometimes depend on local irritation of the genitals, in consequence of pruritus of the external organs, excoriations of the os uteri, or balanitis; or on the presence of worms in the rectum or vagina; these sources of excitement should be looked for, and, if present, should be subjected to appropriate treatment.

T. LAUDER BRUNTON.

ANARTHRIA (ἀν, neg.; and ἄρθρον, a joint).—**SYNON.**: Fr. *Anarthrie*; Ger. *Gliedlösigkeit*.—A term applied to those defects of speech consisting of disordered articulation.

ANASARCA (ἀνά, up; and σάρξ, the flesh).—An effusion of serous fluid into the subcutaneous connective tissues, not limited to a particular locality, but becoming more or less diffused. See DROPSY.

ANEURYSM.—An aneurysm may be defined either as a localised dilatation of an artery; or as a sac, containing fluid or partially coagulated blood, in communication with an artery. It may result from the weakening of the wall of the vessel (1) by disease; (2) from some congenital defect of development; or (3) from direct injury. The disease which most commonly leads to the formation of aneurysm is arterio-sclerosis, especially where syphilis is one of its causal factors. The combination of syphilis, alcoholism, and over-exertion, which frequently occurs in soldiers, renders them specially liable to aneurysm; but it is also common in labourers and in those whose occupation involves the lifting of heavy weights. Its relation to over-strain seems to be indicated by its vastly greater frequency in Great Britain, where the labouring classes work much harder than on the continent of Europe. Acute arteritis, especially the septic form found in malignant endocarditis, where the intima of the aorta is first damaged by the impact of the fragments of the ulcerated valve and then necrosed by the pyogenic organisms which attack it, is an occasional cause of aneurysm of the first part of the aorta. What is termed *embolic aneurysm* may be produced in one of the smaller arteries, such as those of the brain, by the impaction in it either of a calcareous plate derived from an atheromatous aorta, or of a portion of a diseased valve containing micro-organisms. The inner and middle coats in the former case are eroded by the mechanical action of the sharp edge of the calcareous plate, and, in the second, are necrosed by the organisms contained in the embolus. As will be easily understood, such aneurysms are very prone to rupture. The outer coat of an artery as it passes across, or along the wall of, a phthisical cavity in the lung, may be attacked and necrosed by the tubercular process, so that the two inner coats bulge through the weakened spot and produce the so-called *hernial aneurysm*, the rupture of which produces the hæmoptysis that so often proves fatal in advanced pulmonary tuberculosis. Men are more subject to aneurysm than are women, in the proportion of 8 to 1, and they tend to be specially affected between the ages of

40 and 50. Where aneurysm occurs at an early age a congenital defect, a syphilitic lesion, or an embolic origin, may be suspected.

According to their method of formation aneurysms may be fusiform, saccular, or dissecting. The *fusiform* variety is simply a dilatation of a portion of an artery in which the inner and middle coats are more or less degenerated, but in the walls of which all the coats are present. The *saccular* aneurysm is generally produced by the rupture of the inner and middle coats of the artery, frequently as the result of some definite overstrain. A sac is thus produced which communicates with the artery by a small opening, and is bounded externally by the outer coat, with here and there remnants of the inner and middle coats in various stages of fatty and calcareous degeneration. In the *dissecting* variety one or both of the inner coats becomes ruptured, the blood forces its way between the coats for a varying distance, and then either escapes back again into the vessel or, as often happens in aneurysm of the aorta, into the pericardial sac. Such aneurysms have been found extending from the arch of the aorta as far as the division of the abdominal aorta into its two branches. In such cases the aneurysm forms a second tube between the walls, through which the blood passes before it re-enters the channel of the vessel.

The fusiform dilatation of the artery when once established does not necessarily continue to increase, but a saccular aneurysm tends to progressive enlargement, although the rate of this enlargement varies very greatly in different cases. In its growth it causes an irritative proliferation of the surrounding connective tissue, which for a time gives some support to the thinning outer coat of the artery, but in its turn also becomes attenuated by the continuous stretching. If the sac approaches bone or cartilage, it causes absorption of both, but the erosion is much more rapid in the case of bone, as its vascularity favours the occurrence of a rarefying osteitis, whereas the cartilage is merely absorbed from its surface. If the aneurysm approaches a serous membrane, it may cause an obliterative inflammation in the cavity, as is commonly the case in the pleura, or it may rupture into the serous sac before adhesion takes place, as is more frequent in the case of the pericardium. Pressure upon a mucous membrane may lead to its perforation, as frequently occurs in the trachea, and more rarely in the œsophagus and stomach. Pressure upon a blood-vessel may lead to the narrowing and occlusion of the vessel, or to rupture into it, with the establishment of an aneurysmal varix, as may happen, though somewhat rarely, in the superior vena cava. When an aneurysm approaches the skin it seldom ruptures externally, although such a result often appears imminent. When it does, however, death is not necessarily immediate. Saccular aneurysms may contain fluid blood or, more frequently, laminated thrombi. In aneurysm of the larger arteries, it is rare to find any considerable degree of organisation in such thrombi, doubtless owing to the imperfect adhesion of the thrombus to the wall, to the firmness of the clot, to its constant disturbance by the blood-current, and to the degenerate state of the vessel-walls forming the sac. Notwithstanding this, the thrombus breaks to a certain extent the force of the blood-current on the wall of the sac, and has thus a certain remedial power by limiting the constant tendency to expansion, and, when a mucous surface is approached, by

delaying the moment of rupture. See ABDOMINAL ANEURYSM; BRAIN, Aneurysm of; HEART, Aneurysm of; THORACIC ANEURYSM.

ALEXANDER BRUCE.

ANGIECTASIA (ἀγγεῖον, a vessel; and ἔκτασις, extension).—Extension or hypertrophy of the capillaries and minute vessels of the surfaces of the body, especially the skin; hence *angiectasia capillaris*, a term applicable to several forms of vascular nævus. See TUMOURS: *Angioma*.

ANGEIOLEUCITIS (ἀγγεῖον, a vessel; and λευκός, white).—Inflammation of lymphatic vessels. See LYMPHATIC SYSTEM, Diseases of.

ANGINA (ἄγω, I seize by the throat, strangle, or choke).—SYNON.: Fr. *Angine*; Ger. *die Bräune*.

The term *angina* was originally applied to conditions in which difficulty of breathing and of swallowing exist either together or separately, caused by disease situated between the mouth and the lungs, or between the mouth and the stomach. By a special affix to the original term, significative of the seat or the nature of the disease, several morbid processes are known and described, for example:—*angina parotidea*, or mumps; *angina tonsillaris*, or quinsy; *angina laryngea*, or laryngitis; *angina Ludovici*, diffuse suppurative cellulitis in the submaxillary region; *angina pectoris*, or breast-pang; *angina maligna*, or malignant sore-throat; *angina membranosa*, or croup.

ANGINA PECTORIS.—SYNON.: *Syncope Anginosa*; *Angor Pectoris*; Suffocative Breast-pang; Stenocardia. Fr. *Angine de poitrine*; Ger. *Brustbräune*.

DEFINITION.—A paroxysmal affection of the chest, characterised by severe pain, faintness, and anxiety; coming on more or less suddenly; essentially connected with disorders of the pneumogastric, the sympathetic, and spinal nerves, and their branches; and frequently associated with structural disease of the heart and arteries.

ÆTIOLOGY.—In searching for the *causes* of *angina pectoris*, we frequently notice: (1) The well-known conditions which lead to arterio-sclerosis and myocarditis. (2) Morbid changes in the nerve-tissues. (3) The existence of a peculiar condition of the nervous system, which may be described as an undue susceptibility to impressions. It would seem to be often hereditary, and to be found in those temperaments in which there is a high development of the nervous element. (4) The influence of *age* in relation to *angina* is conspicuous; the disease is rare before puberty; and quite eighty per cent. of the cases occur after forty years of age. (5) *Sex* also displays a marked influence among the predisposing causes of this disease. True *angina pectoris* is comparatively rare among women. Out of 49 fatal cases, collected by Forbes, only 2 occurred in females, and out of 15 non-fatal cases only 2—facts which entirely correspond with our experience. In the hysterical temperament a form of spurious or false *angina* is not uncommon. (6) It is associated in many instances with certain habits of life, such as sedentary employments and indulgences at the table, and occasionally with those states of the system termed hysterical. (7) Certain toxic agents, either metabolic as in gout and diabetes, or extraneous, as tobacco and lead.

ANATOMICAL CHARACTERS.—In a few cases no lesions have been found *post mortem*. The following have been the most important changes.

(a) Involvement of the nerves, either of the branches of the cardiac plexus in mediastinal tumours, in aneurysms, and in adherent pericardium, or positive changes in the intrinsic nerves and ganglia, of which there have been a number of observations recorded.

(b) Lesions of the arch of the aorta and of the coronary arteries, which are the most constant anatomical changes. * In the aorta there may be chronic arterio-sclerosis, with much atheroma and calcification, or there may be acute aortitis, as seen in syphilis. The changes in the coronary arteries may be either fibroid or calcareous.

(c) The myocardium may be normal, but in many cases it has been fibroid; in others there has been extensive fatty degeneration. Huchard gives 145 autopsies gathered from the literature. In 17 cases there was mention only of a lesion of the coronary arteries without further specification; of 128 there were 68 with lesions of both coronary arteries, 37 of the left vessel, 15 of the right, and in 12 the seat of the lesion was not stated. In the 128 cases obliteration or stenosis of the vessels had occurred, and of these in 121 there was atheromatous narrowing or thrombosis, in 5 embolism, and in 2 compression.

It may be said that, while there is often in *angina pectoris* an absence of any evident structural disease, the morbid state producing the anginous symptoms may be situated in the medulla oblongata; in the course of the nerves, or in their branches; or in the cardiac ganglia themselves. It may be the result of congestion or inflammation of the nerves, such as occurs in the gouty diathesis; or of other textural changes, such as connective-tissue growth or other growths involving the nerve-fibres and ganglia. An attack may be produced by emotions acting centrifugally; or by irritation acting centripetally, reflected, as just said, through the vaso-motor centre, from impressions made on the peripheral extremities of nerves. Thus acidity of the stomach, the result of indigestion, often gives rise to symptoms which very closely resemble, if they do not constitute, an attack of *angina*. It is by a similar mechanism that anginal symptoms have been produced by irritation reflected from the fifth nerve, as in pivot-teeth; by such irritation of the surface of the skin as results from severe herpes; by cold, or by exposure to wind. But the most frequent source of the symptoms of true *angina* is to be found in those structural affections of the heart already described.

The attack has been ascribed to cramp in the heart-muscles, distension of the chambers, and to an intense neuralgia of the nerves of the heart. Of late years the theory of *intermittent claudication* has been brought forward to explain the phenomena of the attack. Allan Burns, of Glasgow, first formulated the theory in the following terms: 'In health, when we excite the muscular system to more energetic action than usual, we increase the circulation in every part, so that to support this increased action the heart and every other part has its power augmented. If, however, we call into vigorous action a limb round which we have with a moderate degree of tightness applied a ligature, we find that then the member can only support its action for a very short time, for now its supply of energy

and its expenditure do not balance each other; consequently, it soon, from a deficiency of nervous influence and arterial blood, fails and sinks into a state of quiescence. A heart, the coronary vessels of which are cartilaginous or ossified, is in nearly a similar condition; it can, like the limb begirt with a moderately tight ligature, discharge its functions so long as its action is moderate and equal. Increase, however, the action of the whole body, and along with the rest that of the heart, and you will soon see exemplified the truth of what has been said, with this difference, that as there is no interruption to the action of the cardiac nerves, the heart will be able to hold out a little longer than the limb.' This theory has been accepted by Potain, and gives perhaps the most satisfactory explanation of the attack. Irregular action, with weakness of the myocardium, results from the blocking of a main branch or from spasm of the arteries. Not that this or any other theory accounts in full for the agonising character of the pain in the attack; and there are plenty of cases in hospital practice in which we find all the arterial conditions (general and cardiac) which favour intermittent claudication without the history of attacks of pain.

SYMPTOMS.—An attack of angina pectoris commences suddenly with pain in the region of the heart, generally on a level with the lower end of the sternum; occasionally it may be traced from a remote point, following the course of the nerves, even from the ends of the fingers. The pain is severe, and of an oppressive, grasping, crushing, or stabbing character. It extends sometimes across the chest, but more frequently backwards to the scapula, and upwards to the left shoulder and arm. The pain is accompanied by a distressing sense of sinking, of faintness, which causes the patient to seek support, or of impending death. The action of the heart is generally irregular. The pulse at the wrist corresponds; but in many well-marked cases of angina it is tense and resisting, yielding a sphygmographic tracing indicative of extremely high tension, more especially in the early stage of the attack. A fear of aggravating the pain prevents the patient from breathing deeply, though the respiratory function may not be really interfered with. The expression is anxious, the face is pallid, the lips are more or less livid. The whole surface of the body is pale, cold, and covered with a clammy sweat. Flatulence is often present; urine in some cases is passed at short intervals, and generally in abundance.

The attack, more or less severe, having lasted a variable time—from a few minutes to one or two hours—comes to an end, either suddenly or by degrees. The pallor and coldness of the surface are replaced by a uniform glow—the face may even flush; the pulse becomes soft and full; and there is a general feeling of relief. A sense of numbness or tingling occasionally remains along the course of the nerves derived from the brachial and cervical plexuses of the affected side.

All the phenomena of an anginal seizure as above described may be more or less modified. The attack may come on when the patient is at rest, and occasionally it sets in during sleep; but it is more commonly induced by emotion or by physical exertion, especially by walking up an ascent or by exposure to cold air or wind. The pain may be comparatively slight, and as such may recur with interruptions, it may be, during months or even

years, representing anginoid symptoms rather than true angina pectoris. On the other hand it may be so severe as to mark a first, a single, and a fatal attack.

The pain may be almost limited to the region of the heart, or the lower part of the sternum; it may extend all over the chest to both arms, or spread to the sides of the head and neck and down one or both legs; and it may, in some cases, involve the diaphragm. The action of the heart may be slow, weak, and fluttering; or excited and bounding—causing a distressing sense of palpitation; it may be regular or irregular. Obstruction to the circulation from spasm of the arterioles is among the most constant phenomena of the seizure. The breathing sometimes assumes an asthmatic character, with comparatively little pain. There may be much wheezing, and a condition resembling acute emphysema. There may be laryngeal spasm. The mental functions are generally undisturbed; but there is sometimes slight wandering as the attack passes off, and unconsciousness is said to be occasionally observed. The sense of danger of impending death is a characteristic symptom of angina, and one not often absent; while a sensation of gasping or choking, with difficulty in swallowing, is occasionally present. The position of the patient varies. Sometimes he stands, resting his arms on any convenient object; sometimes he stoops or leans forward, unwilling to be disturbed, even to speak. As a rule the attack passes off abruptly, as it commenced, leaving the sufferer free from discomfort; in other cases its disappearance is slow. The varieties in the symptoms of angina pectoris, thus seen to be remarkably numerous, characterise a form of disease which may be comparatively mild and of long duration, or one of intense suffering, hastening to a fatal termination.

COMPLICATIONS.—Among the diseased conditions with which angina pectoris may be said to be associated, rather than complicated, are disorders of the liver and of the digestive organs, gout, renal disease, diabetes, and certain affections of the nervous system. Indeed, so marked is the latter connection, that Trousseau dwelt on the relation which he believed to exist between epilepsy and angina—a relation which seems to depend on that susceptibility to nervous maladies already noticed as presented by some individuals, rather than on any special pathological connection between these two diseases. The subjects of angina may present the features of the so-called Stokes-Adams disease—permanent slow pulse with vertigo, syncope, or epileptic convulsions.

PROGRESS, DURATION, AND TERMINATIONS.—The progress and duration of angina pectoris will depend wholly upon the nature of its cause. Many cases in which a first attack proved fatal have been recorded. The symptoms in these cases were those of the most severe form of angina pectoris. On the other hand, cases present themselves in which symptoms may occur at intervals for years. Thus in many instances individuals present all the symptoms of marked angina, accompanied by most of its distressing phenomena, and by the anxieties and fears that they beget; yet these cases, having a neurotic or gouty origin, are controlled by treatment, the sufferers being restored to health, or continuing for years to enjoy comparative comfort. On the other hand, in the cases in which angina is connected with structural disease of the heart or of

the nerves controlling cardiac action, the attacks progress in frequency and severity, and tend, with more or less certainty, to a fatal termination—it may be within a few days or weeks.

OTHER FORMS OF ANGINA.—Under the terms pseudo-angina, neurotic angina, and angina pectoris vaso-motoria are described cases of cardiac pain which, while it may be of terrible severity, yet experience has taught us is, as a rule, without the gravity of the true angina. Nothnagel brought forward the view that this form is associated with spasm of the arteries, and introduced the term angina pectoris vaso-motoria, under which heading Douglas Powell has grouped the hysterical, toxic, and reflex varieties.

It is by no means easy to make a good classification. The hysterical and neurosthenic varieties are very common, occurring chiefly in women, often persisting for many years, and, while causing great alarm and much distress to the poor victim, they are so rarely fatal that a hopeful prognosis can always be given. Occasionally a fatal termination may happen, as in one case lasting many years, in a young man of twenty-six, a neurosthenic, and much addicted to tobacco, in whose heart and arteries *post mortem* no change whatever could be determined.

DIAGNOSIS.—A typical case of angina pectoris, such as has been already described, can hardly be mistaken. But when the several symptoms constituting an attack are variously modified, some being lessened in severity and others exaggerated; or when these symptoms depend on, so to speak, remote and removable causes; it is often difficult to say how far the disease is what may be regarded as a remediable neuralgia, or an attack of what is commonly recognised as true angina pectoris. So also it may be difficult to say, in cases of true angina, whether the seizure is dependent on structural lesions which admit of no improvement, or on some condition that may be amenable to treatment. But it is with this affection, as with so many others, more difficult to determine the nature of the cause on which the symptoms depend, than merely to recognise the presence of the disease itself. With reference to the diagnosis of the structural diseases of the heart above referred to, it is unnecessary to describe here that which will be found fully treated of under special heads. It remains but to say that in every case the closest scrutiny must be made into the condition of the heart and great blood-vessels, with a view to determine the presence or absence of disease. The investigation must further extend to other viscera, such as the liver and stomach, and to the digestive organs generally, as well as to the several other sources from which symptoms of angina may be excited by the reflected irritation already described. Certain symptoms resulting from the presence of other diseases should not be confounded with angina—such, for example, as the pain and dyspnoea caused by pressure of aneurysms or of tumours within the chest; by rheumatic or gouty neuralgia of the chest-walls; by pleurodynia, or acute pleurisy; or by indigestion, acidity, and flatulence. Each and all of these several conditions must be considered by way of exclusion in determining the nature and origin of the disease.

PROGNOSIS.—In anticipating the future of an attack of angina pectoris, we must be guided chiefly by a knowledge of its cause; in some respects also by its severity; and by the previous history of the case. Thus, if we can ascertain that the attack has

been brought on by some clearly established and removable cause, such as fatigue, a chill, or indigestion, a favourable prognosis may be fairly entertained. On the other hand, if the history of the case tells that there have been several previous attacks, each increasing in severity and connected with heart-disease, we can scarcely avoid being led to the conclusion that the complaint will tend, with more or less rapidity, to a fatal termination. Between these two classes of cases there exist a large majority of instances in which the symptoms of angina, of greater or less severity, depend on neurosis, on gouty diathesis, or on other sources of nerve-disorder, amenable to treatment; and in which, therefore, a favourable prognosis may to some extent be given. But in all cases great caution should be exercised; for many instances occur in which, from slight and obscure beginnings, severe and even fatal examples of the disease have been developed.

TREATMENT.—The treatment of angina pectoris must, first, have reference to relief of the attack itself; and, secondly, during the interval, to the removal, if practicable, of the causes on which the attacks may depend.

During the attack, it is necessary first, if possible, to lessen the patient's anxiety and fear. He should be allowed to retain the position in which he feels most comfort, and an attempt must immediately be made to relieve the suffering. If the exciting cause be one that can be removed, this should be accomplished. For example, if the stomach be full of undigested food, an emetic of mustard might be given with advantage; or if flatulence be present, peppermint, ether, and other antispasmodics will be useful. If cold have produced the seizure, the feet and hands should be immersed in hot water, hot bottles applied to the surface of the body, and poultices of linseed or mustard, or embrocations of chloroform or laudanum, should be applied to the chest. For the more immediate relief of pain some of the agents now known to be effectual for the purpose should be administered. The nitrite of amyl, originally introduced by Lauder Brunton, has been found a more efficient remedy than any other hitherto recommended for the direct relief of the distressing symptoms of the disease. Five or six minims of this drug, which is usually dispensed in capsules, should be carefully inhaled from a handkerchief or piece of lint, and, if necessary, the inhalation may be repeated.

Nitro-glycerin, suggested by Murrell, seems also to act efficiently in doses of $\frac{1}{100}$ grain, in the form of the official tabellæ or 1 per cent. alcoholic solution. The dose may be repeated three or four times at short intervals; but these drugs must be used with caution, as in many cases they produce headache and superficial congestion.

The action of these agents depends on the power they possess of relaxing the arterioles, thus diminishing the peripheral resistance, freeing the heart's action, and readjusting the circulation. As a rule, in the severer paroxysms morphine must be used, and should be given freely. It is to be remembered that, as Burney Yeo pointed out, these patients show a remarkable tolerance of this drug. The inhalation of chloroform may be necessary and is often useful while waiting for the morphine to act.

In those cases in which debility and exhaustion exist, the ordinary stimulants will be required, and various antispasmodics, such as ether, ammonia, &c., may be used. A hypodermic injection of

ether with nitro-glycerin may be given at once. In cases of sudden cardiac failure MacWilliam recommends faradic excitation of the heart, in the form of a series of periodic single induction-shocks, at the normal rate, approximately, of cardiac action. These should be sent through the heart so as to affect the auricles as well as the ventricles, one electrode being applied over the seat of the cardiac impulse, the other over the fourth dorsal vertebra. Large sponge-electrodes should be used, they and the skin being well moistened with salt and water. The shocks employed should be strong—sufficient to excite powerful contraction in the voluntary muscles. In a few cases cardiocentesis has been performed. Inhalations of oxygen are strongly recommended by Douglas Powell.

During the intervals.—It is desirable to avoid all causes likely to bring on an attack of angina, such as mental and sexual excitement, bodily exertion, exposure to cold, and indulgence in indigestible food or heavy meals. The leading principle in treatment, however, should be to endeavour to determine and to remove the cause of the attacks. Whether they depend on organic disease of the heart, on simple neuralgia, on gout or dyspepsia, on debility, or on fulness of habit—to each of such conditions must appropriate treatment, as described in other parts of this work, be directed. The use of tobacco should be prohibited. A variety of specific remedies has been recommended, such as iodide of potassium or sodium in diseased states of the arteries, arsenic, phosphorus, iron, zinc, and the different sedatives and antispasmodics. In cases with a history of syphilis, and in middle-aged men with marked arterio-sclerosis, the use of the iodide may be followed by permanent cure. Bradbury advocates the erythrol tetra-nitrate, which has a very persistent influence upon the blood-pressure. Galvanism, in the form of the continuous current from thirty cells, has proved of use in some uncomplicated cases, the positive pole being placed on the sternum, and the negative on the lower cervical vertebræ. Huchard, in his exhaustive work on angina pectoris, discusses the action of antipyrin and phenacetin, which he regards as useful in false angina. He describes as useless, or even dangerous, the employment of chloral hydrate, atropine, and certain other drugs. Excellent, however, as many of the remedies above named may be under special and suitable circumstances, the result of treatment must entirely depend on the cause of the disease, and how far it is within reach of well-directed agencies. Some cases of apparently severe angina will be found to yield to treatment; while, as might be expected from the nature of the complaint, others unhappily proceed to a fatal termination in spite of every effort directed to their relief.

RICHARD QUAIN.

WILLIAM OSLER.

ANGIOKERATOMA.—This name has been applied to a peculiar superficial form of multiple hæmangioma. The large amount of epithelium covering the lesions causes them to assume a wart-like appearance.

Angiokeratoma makes its appearance in children or in young people and lasts throughout life, but after the patient reaches adult years the disease shows little tendency to increase. The condition affects especially persons who suffer from difficulty or feebleness of the circulation of the blood in the extremities. Thus it is common in those who

suffer from chilblains, and has been seen not infrequently on the extremities of those suffering from lupus erythematosus. The disease does not necessarily involve the actual area affected by chilblains. As the disease progresses, the hands become thickly studded over with small tumours. A congenital tendency to the formation of angiomas also plays a part in the causation of the disease. It has, moreover, been observed that angiokeratoma may appear in several members of the same family.

The chief anatomical lesion consists of well-marked permanent dilatations of the superficial capillaries of the affected part. On section these are obvious to the naked eye, and on microscopic examination are found full of red and white blood-cells and fibrin, which may be seen in various stages of degeneration, where thrombosis has occurred. The dilatations are separated from each other by more or less substantial partitions of connective tissue, in which a certain amount of cellular infiltration may be present. Some observers state that the lymphatic vessels of the part have also undergone dilatation. The cavernous spaces produced in this way ultimately fill the papilla and come in contact with the overlying epithelium.

It is difficult to determine if the hæmangioma thus produced is caused by the permanent dilatation of the pre-existing blood-vessels, or by the formation of new vascular spaces, or by the bursting of the blood-vessels into the lymphatic channels. The amount of epithelial change which takes place is very variable. The epithelium over the affected papilla is usually thin, but between the papillæ it is increased in amount and penetrates deeply into the substance of the tumour. On the whole, a considerable amount of thickening of epithelium occurs, its keratinisation appearing to proceed normally. The stratum granulosum appears always to be present. As the epithelial processes penetrate into the tumour, the cavernous spaces are surrounded, thrombosis occurs, and, the epithelium becoming gradually rubbed off, these spaces show as small dark points on the surface of the tumour.

The disease shows itself in the first instance as small dark red congested spots. In a short time this little area becomes more sharply limited and shows itself as a deep purple spot or papule from two to five millimetres in diameter. By coalescence of neighbouring lesions even larger tumours may make their appearance. On careful examination of the surface minute dark red points may be observed corresponding to the vascular spaces of the angioma. Later, as the epithelium increases in amount and keratosis occurs, the purple spots become raised, hard, and more or less warty. As might be expected, pricking of the surface of the little tumours produces a considerable loss of blood.

When the angiokeratoma has passed into the warty stage, it remains permanent. It is probable, however, that many of the tumours gradually atrophy, leaving small pigmented spots. As a rule, very little inconvenience is caused by the actual presence of the lesions, though occasionally a certain amount of itching is complained of. The lesions are often scattered in large numbers over the affected area, and have no tendency to any special arrangement. They are most usually found on the dorsal and lateral surfaces of the fingers, more rarely on the palmar surfaces. They occupy similar positions on the feet, and they have been observed on the ears and other parts.

The foregoing description of the lesions and their ætiological relationships will enable angiokeratoma to be distinguished from the two conditions most resembling it, verruca vulgaris, and the superficial hæmangioma or lymphangioma.

TREATMENT.—The small tumours may be readily destroyed if necessary by a fine point of the thermo-cautery or galvano-cautery, producing a very minute scar, or they may be very successfully destroyed by careful electrolysis.

JAMES GALLOWAY.

ANGIOMA (ἀγγείον, a vessel).—A tumour consisting mainly of vessels. See TUMOURS.

ANGIONEUROTIC ŒDEMA.—SYNON.: *Acute circumscribed Œdema*; *Quincke's Disease*.—This term is applied to a characteristic form of localised evanescent swelling of the skin.

After slight prodromal symptoms connected with the alimentary tract, swellings appear on the skin with remarkable suddenness, affecting as a rule the face, extremities, and genitals. These swellings take the form of sharply circumscribed tumours varying in size up to that of the palm of the hand. The smaller ones are hemispherical, the larger ones flattened. By coalescence large areas of the skin become affected. The swellings are tense, and present the peculiar waxy or almost translucent appearance suggestive of œdema, or are in some cases reddish in tint. The surrounding skin may be of normal appearance, but is usually erythematous. The tumours persist for a few hours, or as long as two days, and then vanish rapidly. During the attack feelings of tension or warmth may be remarked, but there is a remarkable absence of pruritus or other uncomfortable sensations. Fresh lesions may appear on other parts of the body, and although the duration of each lesion is short, the duration of the attack may extend for an indefinite period. Usually the attack passes off in a few days, but a marked tendency to recurrence is the rule, and after a variable interval a new outbreak appears.

The mucous membranes may become involved, and when the buccal and pharyngeal regions are affected tracheotomy may become necessary. With the exception of such complications, and the discomfort produced by the tumours of the skin, the general health is as a rule maintained. It is reported, however, that albuminuria and hæmoglobinuria have occurred during attacks of the disease.

The disease seems to be the result of sudden exudation of blood-serum into the skin and connective tissues, apparently under the direct control of the vaso-motor nerve-apparatus. It is difficult to associate local irritants with the appearance of the lesions; and any relationship between this disease and disturbance of the functions of the alimentary tract is not nearly so readily established as in the case of the polymorphous erythema, and urticaria, with which angioneurotic œdema has many points in common. A family tendency to this disease has been observed.

TREATMENT.—Local sedative remedies, such as dusting-powders or weak solutions of the liquor plumbi acetatis, may occasionally be used with advantage; but as pruritus gives little trouble, it is usually sufficient to protect the oedematous surfaces from injury. Internal medication has been used freely with very little good result; the administration of ergot and salicin has been strongly

recommended. It is advisable, with our present knowledge, to regulate the diet so as to obtain efficient digestion and assimilation of food, and to avoid articles of food or drugs likely to cause erythematous and urticarial lesions.

Salt-water douches to the spinal region, with subsequent frictions of the skin, have been highly recommended in chronic cases of the disease.

JAMES GALLOWAY.

ANIDROSIS (ἀ, priv.; and ἰδρώς, sweat).—Absence or want of perspiration. See SUDORIPAROUS GLANDS, Diseases of.

ANIDROTICS (ἀ, priv.; and ἰδρώς, sweat).—Agents which check perspiration. See SUDORIPAROUS GLANDS, Diseases of.

ANILINE POISONING.—The aniline dyes, used for dyeing stockings, gloves, &c., are apt to produce an intense form of inflammation and vesication of the skin, which is rebellious against treatment, and liable to relapse many months after the original attack has subsided. See DERMATITIS.

ANILINE, Workers in.—See OCCUPATION DISEASES.

ANKYLOSIS (ἀγκύλος, crooked).—Partial or complete immobility of a joint due to fibrous bands (*fibrous a.*) or to bony union (*bony a.*) between the ends of the bones. When the immobility is due to extra-articular changes, the term *false ankylosis* is employed. See JOINTS, Diseases of.

ANKYLOSTOMA (ἀγκύλος, crooked; and στόμα, a mouth).—A genus of nematode worms. See ENTOZOA.

ANODYNES (ἀ, priv.; and ὁδόνη, pain).—DEFINITION.—Medicines which relieve pain by lessening the excitability of nerves or of nerve centres.

ENUMERATION.—Anodyne medicines include Opium and its alkaloids—Morphine and Codeine; Phenazone (Antipyrine), Acetanilide (Antifebrin), Phenacetin, and Exalgin; Bromide of Potassium; Cannabis indica; Belladonna and its alkaloid—Atropine; Hyoscyamus and Hyoscyamine; Stramonium; Cocaine; β-Eucaine; Aconite and Aconitine; Veratrum and Veratrine; Conium and Conine; Lupulus and Lupulin; Gelsemium; Chloroform, Ether, and their allies; Chloral Hydrate; Butyl-chloral Hydrate; Menthol and Camphor.

ACTION.—Pain is due to a violent stimulation of a sensory nerve being conveyed to some of the encephalic nerve-centres (probably the cerebral hemispheres), and perceived there. The impression produced on all sensory nerves, except the cephalic nerves, is conveyed, for a part of its course, to the head along the spinal cord. The primary impression which is felt as pain is usually made upon the peripheral ends of the sensory nerves; but it may also be made upon their trunks, upon the spinal cord, or possibly upon the encephalic centres directly, without any affection of the nerves themselves, as, for example, hysteria. Pain may therefore be relieved, while the source of irritation still remains, by lessening the excitability of the ends of the sensory nerves which receive the painful impression; of their trunks; of the spinal cord along which the impression travels; or of the encephalic centre in which it is perceived. Opium

act by lessening the excitability of the sensory nerves, the spinal cord, and the encephalic ganglia. Bromide of potassium is also believed to act on all three, although to a much less degree than opium. Phenazone and its allies probably affect the conduction of painful stimuli through the spinal cord or sensory tracts in the brain. Belladonna and atropine affect the sensory nerves, as probably does hyoscyamus. Stramonium, aconite and aconitine, veratrine, chloral hydrate and butyl-chloral hydrate, lupulus and lupulin, and gelsemium probably act on the encephalic centres.

USES.—As opium and morphine act upon all the nervous structures concerned in the production of pain, they may be used to relieve pain whatever its cause. Cannabis indica and bromide of potassium may be employed under the same circumstances as opium, but they have very much less power. Phenazone, acetanilide, phenacetin, and exalgin are powerful analgesics, and relieve pain without disturbing the brain. They are very useful in neuralgic pains, in headaches, and in pain depending on some affections of the spinal cord—for instance, to relieve the lightning-pains in locomotor ataxy. Chloral hydrate seems to relieve pain only by inducing sleep, and does not produce an anæsthetic effect unless it is given in dangerous doses. Butyl-chloral hydrate also induces sleep, but seems to have a special sedative action on the fifth nerve; as likewise has gelsemium—and hence both these agents are used in the treatment of facial neuralgia. As the action of belladonna is exerted chiefly on the peripheral ends of the sensory nerves, this remedy is usually applied directly to the painful part in the form of plaster, liniment, or ointment. Aconite, veratrine, cocaine, and opium are also used as local applications in several forms, for the relief of pain. The various anodynes may be administered not only by the mouth but by other channels, such as by inhalation, by enema or suppository, by hypodermic injection, or by endermic application.

Several therapeutic measures are employed as local anodynes, such as the application of dry or moist heat; cold; electricity; various forms of counter-irritation; acupuncture; and the abstraction of blood.

T. LAUDER BRUNTON.

ANOREXIA (ἀ, priv.; and ὄρεξις, appetite).—Want or deficiency of appetite. See **APETITE**.

ANOSMIA (ἀ, priv.; and ὀσμή, smell).—Loss of the sense of smell. See **NOSE**; and **OLFACTORY NERVE**.

ANTACIDS.—**DEFINITION.**—Medicines used to counteract acidity of the secretions.

ENUMERATION.—The antacids include Potash, Soda, Lithia, Ammonia, Lime, Magnesia and their Carbonates; as well as the salts which the alkalis form with vegetable acids, such as Acetates, Citrates, and Tartrates.

ACTION.—Antacids are divided into: (1) those which act *directly*, lessening acidity in the stomach; and (2) those which act *remotely*, diminishing acidity of the urine. The alkalis and alkaline earths and their carbonates, with the exception of ammonia, have both a direct and remote influence; for when swallowed they act on the stomach, and being absorbed from the intestinal canal, they are excreted by the kidneys, thus lessening the acidity of the urine. Ammonia and its carbonate are direct but not remote antacids; for, although they

neutralise acidity in the stomach, they are partly excreted in the form of urea, and do not diminish the acidity of the urine. The acetates, citrates, and tartrates of the alkalis and alkaline earths, on the other hand, are remote but not direct antacids. They have no antacid effect in the stomach, but undergo combustion in the blood, being converted into carbonates, in which form they are excreted in the urine, and diminish its acidity.

USES.—Excessive acidity of the contents of the stomach gives rise to acid eructations and heartburn. It may sometimes depend on the secretion of a too acid juice by the stomach, but is generally caused by the formation of acid from the decomposition of food when the process of digestion is slow and imperfect. Antacids are given after meals to lessen acidity in the stomach, and afford immediate relief to its attendant symptoms. They may prove even more efficacious by preventing acidity when given before meals (see **ALKALIS**). If the action of the bowels be regular, soda is preferable; but lime should be used if they are relaxed, and magnesia if there is a tendency to constipation. Remote antacids are given to lessen the acidity and irritating qualities of the urine in cystitis and gonorrhœa; and to prevent the deposition of uric acid gravel or calculus in gouty persons. For this purpose potash and lithia are preferable, as their urates are more soluble than those of the other bases. See **ALKALINITY**.

T. LAUDER BRUNTON.

ANTAGONISM.—This term is employed to express the fact that the physiological action of certain substances may be affected, even to the extent of neutralisation, by the presence in the body, at the same time, of other substances having an action of an opposite character. It is important to distinguish between *antidotal action* and *physiological antagonism*. By an *antidote* is meant a substance which so affects the chemical or physical characters of a poison as to prevent its having any injurious action on living animal tissues. Thus acids and alkalis neutralise each other, so as to form innocuous salts; tannin may render tartar emetic and many vegetable alkaloids insoluble; and the hydrated sesquioxide of iron may be used to precipitate arsenious acid. In these cases, the action is limited chiefly to the alimentary canal; and the object of administering the antidote is to form insoluble salts, or compounds which will be physiologically inert. But the *physiological antagonism* of certain substances is presumed to take place in the blood or in the tissues. When such a substance as strychnine, for example, is introduced into the alimentary canal, it is quickly absorbed, and carried by the blood throughout the body. It does not, so far as observation has discovered, influence all the tissues; but it so affects the spinal cord, and possibly the brain, as to give rise to severe tetanic convulsions, chiefly of a reflex character. This effect is, no doubt, due either to some interference in the nutritional changes between the blood and the tissues composing the nerve-centres, or to some specific action of the poison on the nerve-centres themselves. These changes, which are termed physiological, and on which the normal action of the nerve-centres depends, are probably of a molecular or chemical nature; and it is possible to conceive that they may be modified in different ways by different substances. Thus has arisen the

idea of physiological antagonism ; and experiment has shown that, within certain limits, which will no doubt vary in each case, such an antagonism is possible. Antagonism may be either local, affecting one organ, as is seen in the opposite effects upon the pupil of opium or morphine upon the one hand, and stramonium, hyoscyamus, or belladonna upon the other ; or it may extend apparently to more important organs or groups of organs, as in the case of the antagonism between strychnine and the hydrate of chloral. The most important investigations upon the subject of physiological antagonism are the following :—

(1) *Physostigmine and Atropine*, by T. R. Fraser—an inquiry which showed that the fatal effect of three and a half times the minimum fatal dose of physostigmine may be prevented by atropine. (2) *Atropine and Prussic Acid*, a research by Preyer—of a more doubtful character as regards the point to be proved, but still sufficient to show that, within certain limits not yet indicated, it is possible to prevent the fatal action of prussic acid by atropine. (3) *Atropine and Muscarine* (the active principle of *Agaricus muscarius*)—which were found by Schmiedeberg and Koppe to have entirely antagonistic actions on the ganglia of the heart—muscarine exciting the intracardiac inhibitory centres, and stopping the heart in diastole, while atropine has the contrary effect. (4) *Chloral and Strychnine*—an antagonism first pointed out by Oscar Liebreich, who showed that minute doses of strychnine might so rouse an animal from the effects of an overdose of chloral as even to save its life. (5) *Strychnine and Chloral*—with respect to which Hughes Bennett demonstrated the converse of the last-mentioned observation, namely, that in the rabbit a fatal dose of strychnine might be so antagonised by a dose of chloral as to save life. Other examples of antagonism are : chloroform and amyl-nitrite, cocaine and morphine, atropine and jaborandi, strychnine and hydrocyanic acid, thebaine and chloral, and digitalin and aconitine.

CONCLUSIONS.—It has unfortunately to be admitted that the practical results of the preceding researches have not been very encouraging. In all of these investigations it was quite apparent that the limits of physiological antagonism were very narrow. Three elements affect the chances of success in the way of saving life :—(1) the age and strength of the animal ; (2) the amount of the doses of the two active substances—so that if either the one or the other active substance be given slightly in excess, death will probably take place ; and (3) the time between the administration of the two active substances. If the stronger be introduced first, and be allowed to manifest distinctly its physiological action, it is almost impossible to counteract this by that of another substance ; but if the two substances be introduced simultaneously, or if the supposed antagonist to the more active substance be introduced first, the chances of success are much greater. It is apparent, therefore, that the facts relating to physiological antagonism at present known in science do not hold out much hope of good results from their application in practice ; but still the physiological facts are so definite as to indicate a precise mode of treatment. For example, no one acquainted with the investigations mentioned above would hesitate in attempting to relieve the tetanic spasms of a case of poisoning by strychnine by repeated doses of chloral hydrate, or by the

administration of chloroform. A practical result of such researches is that the principle of physiological antagonism may serve as a guide to the application of remedies in disease. Thus excessive secretion, say from mucous membranes or from salivary glands, may be modified or arrested by the use of sulphate of atropine, a striking experimental demonstration of which may be seen in the antagonism between bromal hydrate and sulphate of atropine in the rabbit.

JOHN G. MCKENDRICK.

ANTEFLEXION.—A bending forwards of any organ. The term is specially used in relation to the uterus, when this organ is bent forwards at the line of junction of its body and cervix. *See* UTERUS, Diseases of.

ANTEVERSION.—A displacement forwards of any organ. The term is particularly applied to a change of position of the uterus, in which this organ is bodily displaced in the pelvic cavity, so that the fundus is directed against the bladder, and the cervix towards the sacrum. *See* UTERUS, Diseases of.

ANTHELMINTICS (ἀντί, against ; and ἔλμινς, a worm).—**DEFINITION.**—Medicines which kill or expel intestinal worms.

ENUMERATION.—The principal anthelmintics are :—Oil of Male Fern ; Kamala ; Koussou ; Oil of Turpentine ; Pomegranate Root ; Santonica (Wormseed, so called), and its active principle, Santonin ; Areca ; Mucuna ; Rue ; and drastic purgatives. As purgatives only expel the worms, they are termed *vermifuges* ; while the other anthelmintics which kill the worms are called *vermicides*.

ACTION.—The oil of male fern, kamala, koussou, oil of turpentine, and bark of pomegranate root, act as poisons to tape-worms. Santonica and santonin remove round-worms, and also thread-worms. They were formerly supposed to kill the worms, but it would appear that they only weaken or intoxicate them, so that they are more readily expelled. Castor oil, jalap, scammony, and other purgatives do not kill the worms, but dislodge and expel them, by the increased peristaltic action which they occasion.

USES.—Drastic purgatives may be used for worms of any sort ; areca for both tape- and round-worms ; and the other agents for the worms on which they severally act as poisons. Vermicides are generally given after the patient has fasted for several hours, in order that, the intestines being empty, the drugs may act more readily on the worms. A purgative is usually given some hours afterwards, in order to expel the dead worms. As thread-worms chiefly inhabit the rectum, they are most effectually killed by enemata, which may consist of a strong infusion of quassia ; salt and water ; vinegar and water ; solution of the sulphate or perchloride of iron ; oil of turpentine ; castor oil ; decoction of aloes ; or infusion of senna. As abundance of mucus in the intestines forms a convenient nidus for the growth of worms, anything that diminishes this tends to prevent their occurrence, and for this purpose preparations of iron and bitter tonics are useful.

T. LAUDER BRUNTON.

ANTHRACOSIS (ἀνθραξ, a coal).—A deposit of black material in the tissues or organs. *See* PNEUMOCONIOSIS.

ANTHRAX (ἄνθραξ, a coal).—A synonym for carbuncle, and for malignant pustule. See CARBUNCLE, and PUSTULE, Malignant.

ANTIDOTE (ἀντί, against; and δίδωμι, I give).
DEFINITION.—An antidote is any remedy which, by its physical or its chemical effect upon a poison, or in both ways, is capable of preventing or counteracting the physiological effects of that substance (see ANTAGONISM). Sometimes, however, the term is used in a more comprehensive sense, so as to include the general treatment of a person affected by a particular poison. Thus, in poisoning by opium, the use of the stomach-pump, enforced exertion, chafing the limbs, and artificial respiration may be included in the general antidotal treatment.

MODES OF ACTION, AND APPLICATION.—Most antidotal substances form with the poison insoluble or innocuous compounds. Without attempting to give a complete list, the following are examples of the more common poisons and their respective antidotes:—(1) *arsenious acid*: solution of dialysed iron administered freely, or light magnesia; (2) *prussic acid*: newly precipitated oxide of iron with an alkaline carbonate; hypodermic injection of 2 to 4 m of liquor atropinæ sulphatis every half-hour; (3) *oxalic acid*: chalk, common whiting, or magnesia suspended in water; (4) *tartar emetic*: tannin, catechu, or other vegetable astringents; (5) *acetate of lead*: sulphate of magnesium, or the phosphates of sodium and magnesium; (6) *caustic potash*: dilute acetic acid, fixed oils, lemon-juice; (7) *corrosive sublimate*: albumen, white of egg, flour, or milk; (8) *mineral acids*: chalk, common whiting, plaster from the walls or ceiling, or carbonate of magnesium; (9) *chloride of zinc*: albumen, milk, or carbonate of sodium.

Vegetable poisons cannot thus be counteracted. If they have been taken in the form of seeds, leaves, or roots, the proper course is to remove them from the stomach or bowels as soon as possible by emetics and purgatives, and at the same time to sustain the flagging strength of the patient by the administration of stimulants. On the other hand, if the alkaloid has been taken, it is so soon absorbed that emetics and purgatives are of little avail, or may even be injurious. In these circumstances we must rely on the administration of the physiological antagonist of the poison (such as chloral hydrate in the case of strychnine-poisoning), and on supporting the strength of the patient. The following are the best antidotes to the vegetable poisons most frequently met with:—(1) *aconite root*: emetic of sulphate of zinc and stimulants; (2) *belladonna leaves, berries, or root*: emetic of sulphate of zinc, ammonia, stimulants, and after some time an active purgative; (3) *digitalis*: emetics, stimulants, and the maintenance of the recumbent position; (4) *hyoscyamus leaves*: emetics and stimulants; (5) *hydrochlorate or meconate of morphine, or any of the preparations of opium*: hypodermic injection of apomorphine; external stimulation by warmth, turpentine or camphor liniments; enforced exertion; artificial respiration, and small repeated doses of sulphate of atropine; (6) *chloral hydrate*: the same as for opium; (7) *strychnine or nux vomica*: animal charcoal suspended in water, repeated large doses of chloral hydrate, or chloroform; (8) *atropine*: stimulants, subcutaneous injection of caffeine, morphine, or pilocarpine, or of very minute doses of physostigmine; (9) *calabar bean*: atropine, or

stimulants, artificial respiration; (10) *mushrooms*: subcutaneous injection of 2 to 4 m of liquor atropinæ sulphatis, stimulants, castor oil; (11) *tobacco or nicotine*: stimulants, subcutaneous injection of minute doses of strychnine. See POISONS.

JOHN G. MCKENDRICK.

ANTIMONY, Poisoning by.—See TARTAR EMETIC, Poisoning by.

ANTIPERIODICS.—This term was applied to a group of medicines which were found to prevent or relieve the paroxysms of certain periodically recurring disorders, the nature of which was unknown.

The chief antiperiodics are:—Cinchona-bark and its alkaloids—Quinine, Cinchonine, Quinidine, and Cinchonidine; Salicin, Salicylic Acid and its salts; Eucalyptus globulus; and Arsenic. See MALARIA.

ANTI-PHLOGISTIC (ἀντί, against; and φλέγω, I burn).—A term for any method of treatment that is intended to counteract inflammation and its accompanying constitutional disturbance.

ANTIPYRETICS (ἀντί, against; and πυρετός, a fever).—**DEFINITION.**—Therapeutic agents which reduce the temperature in fever.

ENUMERATION.—The principal agents used as antipyretics are—Cold Baths, Cold Applications, Ice; Diaphoretics; Alcohol; Chloral Hydrate; Quinine; the Salicyl compounds; Phenazone (Antipyrine); Acetanilide (Antifebrin), Phenacetin, and allied bodies; Eucalyptol; Essential Oils; Aconite; Digitalis; Green Hellebore; Purgatives; and Venesection.

ACTION.—The temperature of the body may be reduced, either by increasing the abstraction of heat, or by lessening its production. The direct application of cold, by means of baths, affusion, or sponging, or by enveloping the body in sheets wrung out of cold water, is the most powerful and rapid means of abstracting heat. But the loss of heat which constantly occurs, even in health, by evaporation of the sweat, and the radiation and conduction of heat from the skin, may be increased by the use of diaphoretics, such as salts of potassium, preparations of antimony, or acetate of ammonium, or by such medicines as dilate the cutaneous vessels, so as to allow the heated blood to circulate freely through them, and to become cooled by the external media surrounding the skin. Alcohol, in the form either of wine or spirits, and chloral hydrate have an action of this sort, though alcohol also influences the production of heat. Alcohol, quinine, the salicyl-compounds, antipyrine (phenazone), acetanilide, phenacetin, pyrocin, and their allies, eucalyptol, and essential oils lessen the production of heat within the body, probably by diminishing oxidation of the tissues (see ALCOHOL). Aconite, digitalis, and green hellebore reduce the temperature, but their mode of action is not precisely ascertained.

USES.—Antipyretics act much more powerfully in reducing the temperature of the body in fever than they do in health. They may be used when the temperature has risen either from exposure to a high external temperature, as in thermic fever; in consequence of inflammation, as in pneumonia, pericarditis, or phthisis; or in specific fevers, as acute rheumatism, typhus, and scarlatina. The most rapid and powerful antipyretic remedies are cold baths; next probably come acetanilide, phenazone,

zone, phenacetin, large doses of salicylic acid or salicylate of sodium, and quinine. In acute rheumatism the salicylates are the most useful antipyretics. Quinine seems to act very efficiently in thermic fever when injected subcutaneously. See HYPODERMIC MEDICATION.

T. LAUDER BRUNTON.

ANTIPYRIN-HABIT.—See DRUG-HABITS.

ANTISEPTICS (*ἀντί*, against; and *σηπτικός*, from *σήπω*, I make putrid).—SYNON. : *Antiputrescents*.

DEFINITION.—An antiseptic is a chemical substance that retards or prevents the change in organic materials which is called putrefaction. Putrefaction is the chemical breakdown that occurs in non-living animal or vegetable matter which is brought about by the activity of bacteria and similar micro-organisms. It is usually characterised by the production of malodorous gases. The change is one of the numerous class of phenomena which are called by the general name 'fermentation,' a term originally employed in connection with the production of alcohol and carbon dioxide from sugar through the agency of the yeast-plant. The actual agents that cause this and similar changes are called ferments, and these are generally divided into two groups, the organised and the unorganised. The unorganised ferments or enzymes are chemical substances probably proteid-like in nature; they are shed out by animal or vegetable cells, and the chemical phenomena they produce are usually of the nature of hydrolysis; in some cases they appear to produce oxidation. Diastase, a product of germinating plant-cells, and pepsin, a product of the gastric epithelial cells, are familiar instances of these; the former produces the hydrolytic cleavage of starch into smaller molecules first of dextrin and then of sugar; the latter brings about the similar cleavage of proteid into smaller molecules first of proteose and then of peptone. The enzyme itself does not participate in the composition of the final products. How the organised ferments, like yeast-cells and bacteria, produce their respective decompositions has long been a matter of controversy; here again the actual chemical change is usually hydrolysis. Liebig in 1848 put forward the theory that the organisms that lie at the root of the change shed out what we now call enzymes, and that these chemical substances are the immediate causes of the chemical decomposition. In the case of the *Micrococcus ureæ*, and of the inverting action of yeast, this was proved to be the correct view by the actual separation of active enzymes from the organisms. It is now generally accepted as the correct explanation in all cases; and the experiments recently made by Buchner on yeast are quite conclusive; by crushing the yeast-cells he has succeeded in obtaining from them an enzyme which produces the alcoholic fermentation. The distinction between enzymes and organised ferments, though useful as indicating a difference of degree, has no real foundation as a difference in kind. In all cases the active agent is an enzyme or enzymes, and in all cases these are produced by the activity of living cells.

MODE OF ACTION.—It will be gathered from the preceding paragraph that there are obviously two ways in which an agency can counteract the activity of a micro-organism: (1) it may remove,

destroy, or inhibit the activity of the living cells or organisms; (2) it may remove, or neutralise the enzyme shed out by the organisms. Thus a removal of the organisms by efficient filtration will stop the production of the enzyme and so bring decomposition to a close. All ferments act best in the presence of moisture, and at a temperature somewhat above that of the body. But cold will stop fermentation of any kind, first because it prevents the activity of living cells, and secondly because it inhibits the activity of all chemical agents, including enzymes. It has, however, been shown that even the extremest cold does not kill the organisms in question. On the other hand, a high temperature stops all kinds of fermentation and does so permanently because it destroys the agents that produce the fermentation. Heat acts in one or both of two ways: (1) it kills the micro-organisms; (2) it destroys the enzymes which, as we have seen, are proteid-like in nature, and like most proteids they are coagulated by heat. In the case of the chemical antiseptics, our knowledge is as yet hardly exact enough to state definitely in which of the two ways they may act. Some doubtless act by destroying the protoplasm of the living agents, others by chemically neutralising or precipitating the enzymes, and others again doubtless act in both ways. As a general rule it may be stated that the living protoplasm is more readily affected than the more stable enzymes which they shed out; thus weak solutions of salicylic acid, and chloroform-water are sufficiently strong antiseptics to prevent putrefaction by putting a stop to the growth of micro-organisms, but they will nevertheless allow the action of enzymes to go on without serious impediment. This fact enables an investigator to determine in a mixed case what changes are produced by the one class, and which by the other class of ferments. It is nevertheless important to bear in mind that the difference is only one of degree, in view of the extensive use of antiseptics as preservatives of food. An antiseptic may be beneficial by hindering putrefaction, but it may also be harmful in retarding or even preventing those actions of enzymes which constitute the principal processes that occur during digestion.

ENUMERATION.—The principal antiseptics are the following:—Chlorine, Sulphur Dioxide, Nitric Oxide, Nitrogen Peroxide, Carbolic Acid, Creasote, Benzol, Sulphites, Hyposulphites, and Hypochlorites, Mercuric Chloride, Mercurio-Zinc Cyanide, and several other Mercurial compounds, Zinc Chloride, Arsenious, Chromic, Boric, Tannic, Benzoic, and Salicylic Acids, Borax, Potassium Permanganate, Naphthol, Resorcin, Formaldehyde, Alcohol, Iodoform, Quinine, Charcoal, Common Salt, and Nitre.

USES.—The uses to which antiseptics are applied are numerous; the following are the principal:—

1. As external applications to the body, as in the treatment of skin-diseases due to micro-organisms and similar fungoid growths, e.g. ringworm.

2. As applications to the mucous membranes of the orifices of the body and other readily exposed parts; for instance, in the cleansing of the mouth, teeth, throat, conjunctiva, nasal cavities, vagina, &c. The cleansing of the bladder, where inflammation has been set up by bacterial infection, and of the stomach in similar conditions, may also be included under the same head. The stomach normally

possesses a natural antiseptic in the free hydrochloric acid of the gastric juice.

3. In the treatment of surgical operations and open wounds, carbolic acid and mercurial compounds are the most frequently employed. It is this important branch of treatment which is especially associated with the name of Lister. *See* ANTISEPTIC TREATMENT.

4. In the internal treatment of diseases due to micro-organisms.—This branch of therapeutics is limited by the circumstance that substances which would kill micro-organisms are also inimical to the life of the tissues in which they grow. For instance, the treatment of phthisis by inhalations of such a substance as formalin-vapour has been all but relinquished because of its irritating action on the lungs.

5. As disinfectants. *See* DISINFECTION.

6. As preservatives of anatomical and similar museum-specimens. The preservation of dead bodies as in the process of embalming may also be here mentioned.

7. As preservatives of foods. The difficulty of transport and storage of food for large communities has led to a wholesale use of such substances as borax, boric acid, and formalin for commercial purposes. The practice is to be deprecated because these foreign admixtures are in a greater or less degree poisons to the human body as well as to micro-organisms. This is particularly the case in certain individuals who are abnormally susceptible to such substances. Thus boric acid and borax are often responsible for dyspeptic troubles, and will sometimes cause a skin-eruption like psoriasis. Of the two, borax is more soluble and is the more powerful antiseptic; it also hinders the action of enzymes in the alimentary canal; for instance a very small admixture with borax will completely prevent the curdling action of the rennin-ferment on milk. The use of formalin is still more to be deprecated. It has, even in dilute solutions, a hardening effect on proteid substances, rendering them less digestible, and also has a pronounced inhibitory effect on the digestive enzymes. It appears to be desirable that the practice of adding these and similar foreign substances to food-stuffs should be prohibited, and replaced by a general use of the methods of cold storage and transport.

W. D. HALLIBURTON.

ANTISEPTIC TREATMENT.—PRINCIPLES. The 'Antiseptic System' of treatment, introduced by Lister about 1867, has in great measure revolutionised modern surgery. It depends upon certain postulates, the appreciation and acceptance of which are essential to its successful application. They are:—

I. Septic processes in a wound, and the constitutional changes resulting from them, are caused by the development in it of minute living organisms.

II. These living organisms are (with some few exceptions) always introduced from outside the body, either by the hands or instruments of the operator, by floating particles of dust, by lotions or dressings, or in some similar way.

III. There are means at our disposal, such as the employment of certain germicidal agents, superheating, &c., by which the vitality of these organisms may be destroyed, and their entrance into a wound in an active state effectually prevented, or their influence combated if they be present.

APPLICATIONS.—In order to carry out an antiseptic operation it is necessary:—

1. To purify the skin of the region to be operated upon, for a considerable distance beyond the part which will be occupied by the wound.

2. To purify the hands of the operators, the instruments, sponges, and everything coming in contact with the wound; and to ensure against their defilement until the operation is completed.

3. To prevent any living septic organisms falling upon the wound during an operation, or to destroy their vitality before the dressing is put on.

4. To apply a dressing containing a store of some antiseptic material; and to change it before this material has been so much washed away by the discharges that a track is left along which septic organisms may be able to spread from the edge or surface of the dressing to the wound.

1. **Carbolic Acid** (*Phenol*).—This is occasionally used pure (liquefied by adding 6 to 10 per cent. of water to the crystals) to purify some already septic wounds; or a 1 in 20 watery solution is used for purifying the skin of the part to be operated upon, the hands and instruments of the operator, or in the spray, if that be ever employed. A 1 in 40 watery solution may be used for the sponges, or for bathing the wound during the operation and at the changing of the dressing. Carbolic-acid gauze is not so much used as formerly, but in some cases is still the best dressing at our disposal.

Carbolic acid has the advantages of being very diffusible, and of having an attraction for oily and greasy substances, and hence a superiority over mercurial salts for application to the skin; it does not blacken steel or silver instruments. It has the disadvantage of being irritating, and hence causing more effusion of serum than do the mercurial salts. Dressings containing carbolic acid must be kept in air-tight boxes.

2. **Mercurial Salts.**—(a) *Perchloride of mercury* is employed in solutions of 1 in 500, 1 in 2000, or still weaker. The 1 in 500 solution is used after the carbolic acid lotion, for purifying the skin, or for purifying an already septic wound; the 1 in 2000 solution may be used for the sponges, and for application to a wound during an operation and at the changing of the dressings. Mercuric chloride forms an insoluble albuminate when mixed with blood; hence the solutions are practically much weakened immediately they come into contact with a bleeding surface. Its advantage is its high germicidal quality; its disadvantages are that a 1 in 500 solution applied for some time to the skin causes vesication, and that if mixed with tap-water a large proportion of the salt is thrown down as insoluble chlorides. The latter difficulty is overcome by adding a small quantity of chloride of sodium; or by substituting for the simple corrosive sublimate the very soluble but decidedly irritating *sal alembroth*, a double chloride of ammonium and mercury, which for a while was very largely employed, but is now almost superseded. It is thus obvious that mercuric chloride alone is not a very suitable substance for the active principle of a permanent dressing.

(b) *Biniiodide of mercury* has many of the characteristics of the perchloride; but it does not form so copious a deposit of insoluble albuminates when added to blood. It is more irritating, but is largely used by some surgeons.

(c) *Cyanide of mercury*, in the form of a kind of double salt with *cyanide of zinc*, is the essential constituent of the latest antiseptic dressing (gauze and wool) introduced by Lister. This is very insoluble and very unirritating, but at the same time powerfully antiseptic, and at present promises to take the place of all other materials for a permanent antiseptic dressing.

3. **Boric Acid** is a mild and not very trustworthy antiseptic. It is, however, useful either in the form of boric lint, boric ointment, or boric lotion (a saturated watery solution) for application to superficial granulating surfaces. It is very unirritating.

4. **Salicylic Acid** is also a mild antiseptic. It is used in the form of salicylic wool, as an external dressing outside one containing some more potent material. In powder it is highly irritating to the nasal mucous membrane.

5. **Iodoform** is a powerful deodorant, with a most objectionable smell. Its antiseptic qualities are not great. It is used with great benefit in the form of crystals or powder for application to septic and tuberculous wounds. In the form of gauze it is used for plugging cavities and draining peritoneal incisions.

6. **Chloride of Zinc** in solution—gr. xl. to ʒj.—is invaluable as an application to surfaces which it is necessary to leave exposed to the air, such as those of the mouth or rectum, or for purifying septic cavities. It usually prevents septic changes for two or three days.

7. **Lysol** is very largely used in Germany, and has recently met with some favour in this country. It forms a turbid mixture with water and is very slightly irritating.

8. **Alcohol**, either undiluted or mixed with 15 per cent. of water, has been much extolled. Some surgeons now use no other antiseptic. See ALCOHOL.

This list might be multiplied almost indefinitely, and would have to include various coal-tar products, such as creoline, which is good for application to ulcers, naphthaline, &c., oil of eucalyptus, thymol, iodol, iodine, and countless others, but it is impossible to mention in detail more than those most commonly in use.

USE.—(1) The steps of a simple operation, *where the skin is unbroken*, such as the removal of a tumour or the opening of an abscess, will now be described as an illustration.

The skin of the part to be operated upon, and the hands of the operator, are, with the aid of a nail-brush, washed first with soap and water and usually, though this is of doubtful utility, with turpentine and ether; then with 1 in 20 carbolic acid solution, and then with 1 in 500 sublimate solution. The instruments should have been previously boiled or placed in a flat tray filled with carbolic-acid solution 1 in 20. Knives, scissors, and other cutting instruments may conveniently be sterilised by immersing them in alcohol. A large supply of sublimate-solution, 1 in 2000, or carbolic acid 1 to 40, should be prepared, in which the sponges are to be washed out, and the hands of the surgeon and his assistants dipped from time to time. It is convenient to surround the part to be operated upon with towels wrung out of one of the antiseptic solutions, so that instruments may not be thoughtlessly laid down upon an unpurified surface.

It was formerly the custom to irrigate the wound from time to time during the course of an operation with the weaker mercurial or carbolic-acid lotion.

This is not so frequently done now as formerly, and by many the plan has been quite abandoned. Others thoroughly wash the wound at the conclusion of the operation with boiled water or weak antiseptic solutions before applying the sutures, and during their insertion cover the greater part of the wound with swabs soaked in the same antiseptic solution.

Before changing an antiseptic dressing, scissors and forceps, and a piece of gauze or wool should be placed in a bowl of the antiseptic solution preferred, and the fingers of the surgeon should be similarly purified. As soon as the deep part of the dressing is removed, some of the solution should be dropped upon the wound by means of the gauze or wool, and the process should be frequently repeated until the deep part of the new dressing is in position. The spray has now been almost completely abandoned.

(2) *If the skin have been previously injured*, as in a compound fracture, or in abscesses which have burst, the strongest antiseptic solutions must be applied with great vigour to the exposed surface, their influence being often advantageously supplemented by the use of the sharp spoon or the nail-brush.

Besides these matters the acceptance of the antiseptic principle has effected marvels in the improvement of the hygiene of hospital wards and sick-rooms, by the dressing of septic wounds at frequent intervals with antiseptic and deodorising agents, by proper ventilation, by the methodical purification of bed-pans, catheters, urinals, and other utensils, and in a host of other ways too numerous to mention.

RICKMAN J. GODLEE.

ANTISPASMODICS (ἀντί, against; and σπᾶσμα, a spasm).—DEFINITION.—Medicines which prevent or allay spasm.

ENUMERATION.—Antispasmodics may be arranged in groups as follows:—Valerian, Valerianic Acid and its salts; Musk, Castor, Asafetida, Sumbul and Galbanum; Camphor, Brominated Camphor, Oil of Amber; Ammonia and its Carbonate; Alcohol, Ether, Acetic Ether, Chloroform, Nitrite of Amyl; Bromide of Potassium, Bromide of Ammonium; Conium, Lobelia, Opium, Gelsemium, Indian Hemp, Belladonna, Stramonium; and the Essential Oils. As adjuvants may be mentioned:—Cold Baths, moderate Exercise, Friction, Heat, and Moisture; and also Quinine, Arsenic, Zinc, and Silver.

ACTION.—Certain nerves and nerve-centres, when excited, produce contraction of voluntary or involuntary muscular fibres; other nerves and centres arrest movements; and by the combined action of these two systems the motions of the various contractile structures in the body are regulated, and subordinated to the requirements of the organism as a whole. Excessive contraction or spasm of one part of the body may therefore arise either from excessive action of the motor, or deficient action of the inhibitory centres. Spasm may affect the involuntary muscular fibres of the intestines—as in colic; of the vessels—as in some forms of headache, and in vaso-motor neuroses of the uterus and bladder; of the bronchi—as in spasmodic asthma; of single voluntary muscles, or groups of muscles—as in various forms of cramp; or it may involve the muscular system generally—as in tetanus, epilepsy, and hysteria. Antispasmodics may act by lessening the irritability of motor centres, as, for example, bromide of potassium and conium; or by stimulating those portions of the nervous system

which restrain and co-ordinate movements, as alcohol probably does. There are no direct experiments to show the action of antispasmodics on the inhibitory centres; but it seems probable that they have such an action, although it may not be confined to these parts alone. Thus small doses of alcohol and ether, which stimulate the nervous system generally, and usually increase motor activity, will restrain and co-ordinate excessive muscular action, as in colic, nervous agitation, trembling, and hysteria. It is at present impossible to localise the part of the nervous system affected by valerian, asafetida, and other drugs of this class. As spasms occur when the nervous system is deficient in power, nervine and general tonics, such as quinine, zinc, and iron, are often found to be useful adjuvants.

USES.—In such convulsive diseases as epilepsy, laryngismus stridulus, and infantile convulsions, bromide of potassium is the most powerful antispasmodic; in hysteria—valerian, asafetida, and the bromides; in chorea—arsenic, conium, copper, and zinc; in spasmodic asthma—lobelia and stramonium; in spasm of the blood-vessels—nitrite of amyl. In all spasmodic affections, cold baths or sponging, exposure to sunlight, moderate exercise, and a plain but nutritious diet should be employed; and late hours, a close atmosphere, exhausting emotions, or excessive bodily or mental work should be avoided.

T. LAUDER BRUNTON.

ANTITOXINS: Antitoxic and Antibacterial Serums.—**DEFINITION.**—Antitoxins are substances which are engendered under certain conditions in the bodies of living animals, and which are able to render inactive certain corresponding noxious substances.

Antitoxic Serums.—By treating animals with certain kinds of poisons (toxins), bodies which have the power of rendering these toxins inactive are produced: these are most abundant in the serum of the blood, and are called antitoxins. The scope of action of an antitoxin is limited and specific, in that it neutralises only the particular kind of toxin by means of which it was itself prepared. The kinds of poison which are capable of giving rise to antitoxins are:—(1) *certain bacterial toxins* not yet isolated chemically, such as those made by the *Bacillus pyocyaneus*, and the organisms of diphtheria and tetanus; (2) *certain vegetable poisons* of apparently proteid nature, such as abrin (from jequirity seeds), ricin (from castor oil seeds), and crotin (from croton oil seeds); (3) *snake-venom*, not yet separable from proteids by chemical means; (4) various kinds of *poisonous blood-serum*, one of the most highly toxic of which is that of the eel; (5) *rennet-ferment* and other bodies against which an 'anti'-body has also been prepared. From the above list it will be seen that the 'toxins' for which antitoxins can be made are closely associated with proteid molecules, if indeed they are not essentially proteid in constitution. Attempts to prepare antitoxins to alkaloids, such as morphine and strychnine, have all failed.

Antibacterial Serums.—Besides the bacterial toxins mentioned, many kinds of bacteria or their products may be used for the immunisation of animals, in which process 'anti-bodies' are formed. These, however, have no effect upon the essential toxin of the bacteria, although they exert a definite influence upon the bacteria themselves

(destructive or bacteriolytic, and inhibitory to growth), and are therefore called *antibacterial*. In the case of the organisms of cholera, typhoid fever, &c., only this form of serum has yet been obtained, while in that of the *Bacillus pyocyaneus* both antitoxic and antibacterial serums have been made by appropriate methods. Since antibacterial serums have no power of neutralising toxins, they are not of much use for therapeutic purposes.

Care must be taken not to confuse the liquids containing bacilli and their products, such as are used for giving protection against typhoid fever, plague, &c., with antitoxins. Even in medical literature the former are sometimes referred to erroneously as serums.

MODE OF PREPARATION.—The horse has been chosen as the most useful large animal for the production of antitoxin, one point of value being the low degree of toxicity of its serum for man. The general principle is to give the animal gradually increasing quantities of the desired toxin until it is able to endure a very considerable multiple of what would at first have been a certainly fatal dose. It is generally advisable to give doses sufficiently large to cause a considerable febrile disturbance. After a given interval has elapsed, several litres of blood are removed, with strict precautions against the occurrence of accidental bacterial contamination. The blood withdrawn is allowed to clot, and the serum is removed by sterilised apparatus as soon as it has separated; a small proportion of an antiseptic (such as phenol 0.5 per cent., or trikresol 0.4 per cent.) is then added, and the serum thus prepared is allowed to stand to facilitate the settlement and subsequent removal of any sediment which may tend to form. The resulting fluid is usually passed through germ-proof filters by means of pressure, and is then measured off into quantities suitable for single doses, which vary according to its potency; these are either placed in phials or sealed in tubes. All the manipulations are carried out with sterilised apparatus and strict aseptic precautions. To prevent the risk of distributing glanders or tuberculosis, the animal is given test-injections of mallein and tuberculin before the immunising treatment is carried out.

At the commencement it is advisable to give a foundation-immunity by injecting toxins which have been modified in certain ways (toxoids)—thus in the case of diphtheria the filtered culture may be heated to 60°–70° C., and in the case of tetanus the filtered culture is modified by the addition of carbon disulphide. Some authors recommend a course of injections of antitoxin before or during the toxin-treatment. The actual details of the treatment cannot be given here, since the production is largely for commercial purposes, and some of the methods employed are of the nature of trade-secrets. The mere feeding of animals on some poisons such as ricin and abrin may cause the appearance of antitoxins in the blood; but this does not occur with the toxin of tetanus or of diphtheria. The serum may be dried, generally upon flat plates, when it assumes the form of brittle scales; for use these are dissolved in recently boiled (sterile) water which has been allowed to cool.

Concentrated serums are also made by freezing and thawing repeatedly; by these procedures much water can be removed. Diphtheria-antitoxin, as at present used, seldom has less than 250 antitoxic units (*v. infra*) in each cubic centimetre; but it has been obtained with as many as 1,250 units; possibly

in the future still more potent preparations will be available.

The *antibacterial* class of serum is produced by injecting into an animal gradually increasing doses of whole cultures (i.e. bacteria with or without their products); the organisms may be previously killed by means of heat (60° C.) or antiseptics (e.g. chloroform); or they may be given in the living condition, but the latter method is not so safe for the worker.

Poisons giving rise to the formation of antitoxins.—The toxins present in the filtrates of cultures of the bacilli of diphtheria, tetanus, and botulism are the types of bodies which will lead to the production of antitoxins.

There are many pathogenic bacteria to the toxins of which living animals have no power of forming antitoxins. Thus highly toxic products are formed in cultures of the gonococcus and of the influenza-bacillus, but hitherto endeavours to get even a semblance of *antitoxin* for these have failed. In the case of the bacteria of plague, enteric fever, pneumonia, and erysipelas, no satisfactory toxin (that is, one which is at all comparable to those of diphtheria and tetanus) has yet been made; the same is true in the case of cholera. Attempts to produce *antibacterial serums* for the influenza-bacillus and the gonococcus have also failed, nor has any success been attained with the bacterium of fowl-cholera—a matter which is of interest in that this was one of the first microbes against which an active immunity was produced by Pasteur. For plague-bacilli, typhoid-bacilli, streptococci, and cholera-vibrios antibacterial serums can be prepared, which possess in some cases a high degree of potency (e.g. 1 cubic millimetre of good typhoid-serum will quite prevent the action of 10–12 fatal doses of highly virulent bacilli).

Since we do not know whether the proper toxins of these bacilli can be produced artificially, we cannot tell whether they possess the chemical constitution necessary for the production of antitoxins. Thus certain poisonous bodies such as alkaloids (morphine, strychnine, &c.) appear to be incapable of causing the formation of antitoxin, although a certain amount of individual tolerance may be attainable in some cases. The chemical nature of the poisons of the antitoxin-producing type (diphtheria, tetanus, and botulism) is not yet completely known, but the observations of Brieger and Boer tend to the conclusion that they are not proteids. It is, however, difficult, if not impossible, to isolate them entirely from what is possibly adherent proteid. The poisons of jequirity and ricinus &c. seeds are also either proteid or linked on to proteid molecules; the same is true of snake-venom.

NATURE OF ANTITOXIN.—Complete knowledge of the chemical nature of antitoxin is not yet forthcoming. Most observers are agreed that antitoxin has some connection with globulins, for precipitants of these bodies (saturation with neutral salts, &c.) carry down the antitoxin. Antitoxin probably has a large molecule, since it will not dialyse nor will it pass through a gelatine-choked filter (C. J. Martin); in these points it resembles globulin. It is closely allied in these and other characters to the active matter of antibacterial, antihæmal, and agglutinating serums.

It appears that when carbon dioxide is used to precipitate globulin the antitoxin is destroyed.

Heating up to temperatures below 60° C. for half

an hour has little if any effect upon the activity of most antitoxins, though prolonged periods of exposure cause some alteration; higher temperatures, as from 60° to 70° C., cause weakening or destruction according to the length and degree of the heating.

Strong *Light* has considerable destructive effect; but the diffused daylight in a room may cause no appreciable loss of activity after several months' exposure. On analysis it is found that actinic rays (blue and green) cause marked loss in a few months, while the more non-actinic rays (yellow and red) have very little effect in the same time.

Exposure to oxygen and air has a deleterious effect.

In well-filled bottles shielded from light but kept at ordinary room-temperature, antidiphtheric serum has been kept for several years without impairment; at body-temperature there appears to be some deterioration in much shorter time. Anti-venomous serum has been re-tested after a journey to and from the tropics and found unimpaired. Where the maintenance of exact degrees of potency is important, as in the case of standard serum for testing purposes, the serum is dried completely (eventually by the aid of anhydrous phosphoric acid), and kept *in vacuo*.

MODE OF ACTION OF ANTITOXIN.—An antitoxin only possesses the power of neutralising the corresponding toxin—thus diphtheria-antitoxin neutralises diphtheria-toxin but not tetanus-toxin, antiabrin does not affect ricin, and so on; in the case of antivenene there is perhaps some slight capacity for acting upon the venoms of different kinds of snakes, but this is limited in extent. Similar limitations are found in the case of antibacterial serums; thus there is no reason to think that an infection with staphylococci is benefited more by a dose of antistreptococcic serum than by the serum of an untreated animal.

Formerly it was thought that the action of antitoxin upon toxin only took place by aid of living tissue-elements; thus Metchnikoff introduced the term 'stimuline,' for he thought that the antitoxin stimulated the cells (especially leucocytes) to resist the toxin. Experimental evidence however is in favour of a *direct action* of a chemical nature between the two bodies, analogous to that of an acid and a base or to the formation of a double salt (Ehrlich). Toxin is neutralised by antitoxin only when the two substances come into contact with each other. Thus a quantity of antitoxin which will exactly neutralise a given amount of toxin when the two are mixed together and injected subcutaneously into an animal is not sufficient to nullify the action of the toxin when the two are given separately in different parts of the animal; in the latter case some 10 to 20 times the quantity of serum may be required to prevent the death of the animal, even though the one to which the mixed dose (containing only $\frac{1}{20}$ as much antitoxin) has been given may show no trace of illness or lesion. A given quantity of antitoxin will neutralise a given quantity of free toxin; from this it follows that the 'law of multiples' should hold good—that is, ten times the quantity of serum should neutralise ten times the quantity of toxin. This has been found to be the case with snake-venom; and even with the extremely complex filtrates of diphtheria-cultures the results obtained by giving thousandfold quantities (Cobbett) are surprisingly close to the theoretical effect which should be obtained. Divergences which occur

are thought to be due to the presence of other poisons which are not capable of union with antitoxin.

Earlier experimenters thought that in a neutral mixture the antitoxin and toxin remained side by side without mutual action, until they were introduced into a living animal; for if means were used to destroy the one but not the other, undestroyed antitoxin or toxin (according to circumstances) was found in the free condition. It has since been shown that this is only the case when sufficient time has not been allowed for the mutual interaction to take place. This action takes place more rapidly in concentrated than in dilute solutions, and in the warm than in the cold. Martin and Cherry made mixtures consisting of 1 c.c. of antivenomous serum with three times the fatal dose of the heat-resisting constituent of snake-venom; after leaving them in contact for various periods of time the mixtures were exposed to a temperature of 68° C. for ten minutes, whereby the antitoxin is entirely destroyed. An animal which was injected with the unheated mixture remained entirely without symptoms of poisoning; so also did one which received a dose kept thirty minutes before heating. Those which were given doses kept ten and fifteen minutes were severely ill but recovered; while those which received doses which had only been mixed two and five minutes before heating died with symptoms of poisoning. These experiments show that the serum was capable of completely neutralising the venom if sufficient time was allowed for their interaction. Similar effects have been obtained with other toxins and their respective serums.

It has been found (Ehrlich) that toxins may become modified and lose their toxicity, but that notwithstanding this they are still capable of action upon antitoxin. When different preparations of filtered diphtheria-cultures are tested against *exactly the same amount of antitoxin*, it is found that in a completely neutral physiological mixture in one case there may be only 20 toxic units, or there may be as many as 120. Again, in one and the same filtrate the toxicity diminishes on keeping, but the amount of antitoxin necessary to produce a physiologically neutral mixture remains constant, although the toxicity may have sunk to one-third of that originally present. Such facts are clearly explained by Ehrlich as showing that the filtrate contains the same number of equivalents which are capable of combining with the unit-quantity of antitoxin; and those molecules of toxin which have altered so as to lose their toxicity he calls *toxoids*.

ESTIMATION OF ANTITOXIC POWER OF SERUMS.—The method used for the measurement of diphtheria-antitoxin will form an example. In earlier days measurement was attempted by ascertaining what quantity of serum was necessary to prevent the action of a tenfold minimal fatal dose, but from what has just been said it will be clear that this method soon had to be given up. In dealing with questions involving the use of minimal fatal doses, it should be remembered that an animal is able to overcome a certain amount of poison up to the *maximal non-fatal dose*; by adding a small excess, merely a fraction of this maximal non-fatal dose, it becomes a fatal dose. A so-called tenfold fatal dose is the sum of ten components, each consisting of one maximal non-fatal dose with the addition of a fractional part of this sufficient to ensure death. It is only the nine and the fractional parts which have to be

neutralised to ensure the survival of the animal. The test is now made by comparing the action of the unknown serum with that of *standard serum*, which is kept dry *in vacuo* (see above), upon a toxic culture-filtrate which has been kept under toluol for some months; filtrates are not suitable for use until the loss of toxicity which occurs at first has ceased, and they have become stable. In order to avoid errors arising from the varying susceptibility of animals, young guinea-pigs of 250 to 280 grammes weight are used, and the criterion is death on the fourth day. The injection of mixed toxin and serum is made accurately in the subcutaneous tissue. The *antitoxin unit* was founded originally on the amount of antitoxin requisite to neutralise a tenfold fatal dose of the toxin; this quantity was taken as one-tenth of a unit; a unit therefore completely neutralised one hundred fatal doses. The *unit (antitoxin or immunisation unit)* is now measured by means of the standard dried serum, which is kept for comparison, and, roughly speaking, it is effective in nullifying about 100 fatal doses. Ehrlich's improved method is to measure out equal quantities of a solution of known strength made from standard dry serum, each of which shall contain *one unit of antitoxin*. Each dose is made up to 4 c.c. with saline solution, and after being mixed with measured quantities of stable toxin-solution is injected subcutaneously. By varying the quantities of toxin the amount is found which, when mixed with one unit of antitoxin, will just kill the animal upon the fourth day; this quantity of the toxin forms the test-dose. In order to ensure that a serum of unknown strength possesses not less than a given number of units, a corresponding quantity is mixed with the test-dose of toxin; should the animal die in the four days the serum does not possess the given strength, while if it die on the fifth or sixth day an allowance of five to ten per cent. is recommended, in order that the dose-strength claimed should not be too close to the border line.

MODE OF ACTION OF ANTI-BACTERIAL SERUM. It is not settled whether the essential action of anti-bacterial serum is direct (as the writer believes) or indirect, taking place through the agency of the living tissues. The frequent presence of the qualities of inhibiting the growth of, or of agglutinating, the bacillus in question cannot be discussed here. As might be expected when a living virus is given, there is no *law of multiples* (such as may be found with non-living toxin) when appropriate quantities of serum are added to the doses. Thus, with certain bacteria, such as those of typhoid fever or cholera, a minute quantity of active serum added to ten times the smallest certainly fatal dose may safely ward off all signs of illness, but, on the other hand, 200 times as much serum may not prevent death from thirty fatal doses. With certain other bacteria of which the virulence can be raised to so high a pitch that nine or ten germs may be enough to cause death (e.g. pneumococcus), 1 or 2 c.c. of efficient serum may be enough to secure the safety of the animal, although as many as 20,000 fatal doses are given with it (Pane). Anti-bacterial serums do not possess antitoxic power, although antitoxic serums always possess some, and it may be considerable, power of inhibiting the action of living bacteria. Some bacteria, such as the *Bacillus pyocyaneus*, will yield a toxin, whereby an antitoxic serum can be produced, while by treating an animal with the living culture an anti-bacterial serum can be pre-

pared. Wassermann has prepared these two forms of serum by treating a goat first for a period with toxin and later with living culture. At the end of the first period the antitoxic power was such that 0.5 c.c. would protect against four fatal doses of toxin, and 0.2 c.c. was effective against a fivefold fatal dose of living bacilli; at the end of the second period 0.005 c.c. protected against the fivefold living dose, but 1 c.c. had no retarding action on the fourfold fatal dose of toxin. From numerous experiments by different authors, it appears that anti-bacterial serums are of no value for therapeutical purposes in cases where the neutralisation of toxins is essential.

Antibacterial serums are of great value for the precise recognition of certain bacteria, such as those of cholera and typhoid fever. This is effected (Pfeiffer) by mixing about a tenfold fatal dose of a young culture (the fatal dose should not exceed about $\frac{1}{10}$ to $\frac{1}{2}$ milligramme of bacteria) with a few cubic millimetres of efficient serum. The mixture is injected into the peritoneal cavity of a guinea-pig, and samples of the peritoneal fluid are examined after the lapse of about $\frac{1}{2}$ to 1 hour; at the end of this time, if the bacterium is of the same sort as that with which the serum was prepared, all the bacteria will be found to have degenerated into coccus-like bodies; in a 'control' animal, unaltered bacteria will be seen if the culture has the requisite virulence for the test.

As in the case of antitoxins the action is specific in so far as it is not manifested when quite unrelated forms of bacteria are tested; when closely allied forms are tried, it is subject to slight limitations, but probably to a less extent than is the case with the clumping action which most of these serums also possess. For these tests the serums must be free from added antiseptics.

DISTRIBUTION AND SITE OF ORIGIN OF ANTITOXIC AND ANTIBACTERIAL BODIES.—It has been found that the specific substances appear earlier and in greater quantity in the blood-forming organs (lymphatic glands, spleen, bone-marrow) than in the blood after inoculation with cultures. As they disappear from these organs the quantity in the blood increases, and it is inferred from this that these organs are the sites of production of the specific substances. In the case of antitoxins the matter has not yet been followed out with the same thoroughness. In both cases it is fairly certain that the production does not occur directly from the constituents of the circulating blood. The tendency is for the substances to accumulate in the blood, and they may remain in recognisable quantity for long periods after cessation of the active or direct immunisation; on the other hand, when passive immunisation is carried out (i.e. by injecting antitoxin), they gradually disappear, especially when the serum injected is obtained from a different species of animal. The duration of the immunity is dependent partly also on the quantity of antitoxin given, the ordinary dose of 200 to 300 immunisation-units of diphtheria-antitoxin for prophylactic use remains effective for about three weeks. It should be remembered that there may be sufficient 'anti-substance' in the whole blood to protect against further attack although the amount in the small quantities which can be used for testing may not be determinable. The 'anti-substances' (antitoxic, antibacterial, and clumping) also pass out in the milk and some other secretions. They do not pass into the urine unless the kidney is damaged.

Bile of normal animals (probably certain of its protoid constituents) has considerable power of destroying many of the toxins, but we do not know that the action is that of true antitoxin. In certain cases, however, distinct indication of specific substances can be found in treated animals. Thus, the bile of an animal dead of rabies has preventive action when mixed with virulent rabies-material, while that of a normal animal has none. The substance of the central nervous system has a power of neutralising certain toxins (those of tetanus and botulism, but not that of diphtheria) when mixed with them. It is not at all certain that this action is really due to the presence of an antitoxin, for it appears that the effective agent is not soluble, while some other substances, like carmine, have a similar power.

THEORIES OF ORIGIN OF ANTITOXINS.—Various theories have been propounded to account for the nature of antitoxin; it has been suggested (1) that antitoxin is modified toxin (there is no evidence in support of this); (2) that it is secreted by the tissues solely in consequence of the presence of a given toxin; and (3) that it is present in normal animals, but that its production can be increased by the exhibition of the given toxin. The last theory is at present most in vogue and finds its explanation in the 'Side-chain' theory of Ehrlich. Ehrlich pictures the cell-protoplasm as possessing a number of different chemical molecular groups (side-chains) in its chemical constitution; each of these has a peculiar affinity for particular substances whereby the ordinary nutrition of the cell with various substances is effected. The protoplasm of any cell contains a number of different 'side-chain' molecules, each of which only picks up the kind of substance for which it has an affinity. The toxin-molecule is pictured as consisting of two parts, one of which (toxophore) is the essentially poisonous agent, while the other (haptophore) is the means whereby the toxin-molecule becomes fixed to an appropriate side-chain. If the toxophoric group is destroyed the haptophore (toxoid) may remain and no noxious action is produced; if the haptophore is attached to a liberated side-chain the combined group has no power of again fixing itself, and becomes harmless. The side-chain thus has the power of neutralising the given toxin-molecule. Antitoxin (for instance, in serum) simply consists, according to this theory, of side-chains which have become detached from cell-protoplasm. By means of treatment of an animal with a toxin the cells are stimulated to produce an unnecessarily large quantity of appropriate side-chains (overproduction): these are liberated into the blood-stream and the antitoxic power of the serum rises. On this theory it should be possible to produce antitoxin by the aid of the haptophoric group only (toxoids), and at any rate a foundation-immunity can be thus obtained. It is suggested that the injection of toxoids may be useful for therapeutical purposes by inducing the production of antitoxic side-chain molecules before the production of toxin by the infecting agent has become too great. According to this theory antitoxin is produced only in tissue-cells in which appropriate side-chains exist, and consequently different antitoxins may be formed in different tissues or organs. There is much yet to be done before this theory can pass beyond the realm of a 'working hypothesis,' but as such it has already led to advance in our knowledge.

THERAPEUTICAL ACTION OF ANTITOXINS.—It has already been stated that the maximum effect of antitoxin is obtained when the toxin and antitoxin are brought into contact before they are introduced into an animal. It is found that as the interval between the introduction of the toxin and the subsequent injection of the antitoxin is increased, so the amount of the latter which is necessary to banish symptoms also increases, but in a disproportionately rapid ratio, so that at last it is no longer possible to prevent death even when enormous multiples of the dose requisite to make a physiologically neutral mixture are given. The following instance (Dönitz) will serve as an illustration: a series of rabbits received twelve fatal doses of tetanus-toxin each at various intervals after 600 neutralising doses of antitoxin were given (in each case directly into the veins); when the interval was two and three-quarter hours no tetanic symptoms occurred; when four hours, only a few animals recovered, and all these had more or less severe tetanus; while, if an interval of five hours had elapsed, not a single animal survived. In another series two fatal doses were given, and it was found that a like amount of serum (as above) did not prevent death if there was an interval of twenty-four or more hours. It is therefore inferred that a combination of toxin with the tissues occurs; at first this is loose and can be upset by the antitoxin; later it becomes so firmly bound that antitoxin is unable to withdraw the toxin and neutralise it. In severe poisoning with tetanus at least one fatal dose is thus firmly bound out of reach of antitoxin in the short period of four to eight minutes in rabbits. Similar effects are produced with diphtheria-toxin, the fixation by the tissues not being quite so rapid. *It is of paramount importance to commence antitoxin treatment at the earliest possible moment in order to forestall the formation of an indissoluble union of the toxin with the tissue-elements. As time advances the value of antitoxin becomes rapidly less until it is no longer of avail.* It will be clear that for studying the statistics of serum-treatment a knowledge of the period of the disease at which it was administered is of great importance, as is shown by the following figures for diphtheria, taken from the Transactions of the Clinical Society of London (1898 Antitoxin Committee):—

	Treatment commenced on				
	1st day	2nd day	3rd day	4th day	5th day and after
Mortality, p.c.:					
No antitoxin	22·5	27·0	29·4	31·6	36·8
Antitoxin	10·0	10·8	15·0	20·0	25·5

The effect of antitoxin-treatment is very strikingly shown by the mortality in tracheotomy-cases; figures taken from the same source show a mortality of 16 per cent. when antitoxin was given within the first three days; 40·7 per cent. in cases treated within the next three days; and 64·7 per cent. in those treated on and after the seventh day; the general mortality without antitoxin varies between 60 and 75 per cent. It will be perceived that the mere presentation of the mortality of cases is not sufficiently exact to show the real effect of serum-treatment. In tetanus the cases which have been collected are less numerous; before antitoxin was introduced the death-rate was 96·7 per cent. (Poland) when the incubation-period was less than ten days, while in 48 cases treated with

antitoxin (Köhler) with the same limit of incubation the death-rate was 43·8 per cent.; and in twenty such cases where the treatment was begun in the first two days after the onset of symptoms it fell to 64·5 per cent. But since much improvement has recently been made in the potency of antitetanic serum there is ground for hope that future results may be still more successful.

MODES OF ADMINISTRATION.—Scrupulous attention to asepsis is absolutely necessary. The skin is cleansed with soap or solution of caustic alkali followed by some antiseptic, and the syringe is made absolutely sterile by boiling. The site of injection is usually under the loose skin in the flank. The dose required is regulated by units of potency, and not by the quantity injected. It is advisable to keep careful record of the time of administration, the exact dose used, and the effects produced in the patient.

Direct injection into the veins is not to be recommended on account of the enhanced effect of the toxic action of the serum of one species of animal upon another when introduced by this method. This toxic action has no relation to the antitoxin or to the nature of the toxin-treatment of the animal supplying the serum, for it is found to exist in the serum of normal animals of the same kind. Individuals among mankind as well as among the lower animals have a varying susceptibility to these toxic substances. A few cases have been recorded where human beings have succumbed or shown great symptoms of distress within a few minutes of an injection. An instance is given by Rauschenbusch in which five children and two servants received prophylactic injections from a single bottle of serum, the quantity amounting in each case to 0·8 c.c.; one of them, a child of ten, became suddenly ill—the symptoms being giddiness and faintness, vomiting and cutaneous irritation with urticarial wheals—within a few minutes of the injection. Eight hours later she still felt ill, but was nearly well on the following day. The symptoms and rapid onset noted in this case are exactly similar to those seen in susceptible guinea-pigs. The other four persons showed not the slightest ill effect. A few isolated cases are recorded where death has occurred apparently from a similar high susceptibility, but these are infinitesimal in proportion to the many thousands of persons to whom injections, often in large quantity, have been administered without any harm ensuing. Besides these immediate toxic effects the injection of the serum of horses may cause remote disturbances, which again do not appear to bear any very definite relation to the amount of serum injected. The most frequent of these effects are *rashes*—erythematous, scarlatiniform, urticarial, or more rarely morbilliform. They commonly appear in the second week after injection, and do not as a rule last more than about four days. Out of 9581 cases examined by the German Collective Investigation rashes occurred in 678 instances: the statistics collected by the Clinical Society of London give as many as 33 per cent., but only 633 cases of injections were investigated. Joint-pains with or without swelling may also occur. The temperature may be raised, but there is no evidence of a deleterious action on the kidneys. Similar effects may be produced by any of the serums (antitetanic, antistreptococcic, &c.), for they are dependent upon the fact that it is horse-serum, which is about the least toxic of animal serums for man. The entire elimination of the

noxious bodies and the preparation of a pure antitoxin are problems for future investigation.

Absorption of Antitoxin from Mucous Surfaces.—Experimentally antitoxin is not absorbed when given by mouth or rectum; 1000 times the dose which will neutralise and stay an intoxication when given under the skin has not the slightest effect upon the course of the poisoning when given by mouth or rectum. This mode of administration in acute conditions is merely to be regarded as a waste of valuable serum. It appears however that some of the immunity which is transmitted to suckling animals from the mother is acquired through the milk. Thus Ehrlich showed that normal sucklings when nurtured by an immunised foster-mother acquired some degree of immunity, while the milk of the foster-mother was proved to contain antitoxin. It is possible that long-continued administration by the mouth may lead in adults to a sufficient absorption of immunising substances for protective purposes, but this is of no value for the treatment of disease where time is important.

Finally a few notes of the serums which are in use may be appended:—

Diphtheria. Nature—antitoxic. Prepared by treatment with filtered germ-free cultures. For therapeutic use 1000 to 6000 units or more are given and repeated if necessary. Some recent observations give promise of reduction in frequency of the occurrence of paralysis by continuing the injections after immediate danger has disappeared. For prophylaxis 200 to 300 units are given; the protection lasts about three weeks.

Tetanus. Nature—antitoxic. Prepared by treatment with modified (toxoid) and active germ-free toxins. Immediate effects of the serum are not probable, since symptoms are probably due to toxin which has been fixed many hours before. Serum should be persevered with, if used, on account of the capacity of the tissues for fixing the toxin. Intracerebral injections may be given, following Roux and Borrel's experiments. (Rambaud collected sixteen cases with seven recoveries.) Prophylactic injections have been given in infected puerperal wards and to horses with satisfactory (negative) results.

Streptococcus. Nature—antibacterial. Prepared by treatment with cultures. Much difference of opinion exists as to its value both in the laboratory and at the bedside. The probable explanation is found in the observation that there are several varieties of streptococci, each of which is unaffected by serum prepared by means of any of the other varieties. Many clinical reports of apparent good effects are vitiated by want of demonstration that the condition of the patient was due to streptococci and by the impossibility of eliminating the possible effects of other methods of treatment (uterine douches, &c.).

Pneumonia. Probably more antibacterial than antitoxic. Prepared by treatment with cultures. In the laboratory the serum is highly effective; moreover its action on varieties is not so limited as is the case with the streptococci. Not yet sufficiently tried on man.

Plague. Nature—doubtful; has some slight antitoxic action. Prepared by treatment with living, dead, or filtered cultures. Good results have been obtained in laboratory experiments; it probably has some value for treating man. It has been used for prophylaxis in man, but is not to be confused with

Haffkine's preventive material, which consists of killed bacilli.

Typhoid and Cholera. Nature—antibacterial. Prepared as last. In the laboratory they are highly effective for preventing infection, but of no curative value for highly acute infections. The effects produced on enteric fever and cholera respectively in man are not very well marked, but they are probably not entirely without some, if light, efficacy. They have been used for prophylaxis, but are not to be confused with Wright's and Haffkine's preventive treatment with killed bacilli.

Snake-venom. Nature—antitoxic. Prepared by treatment with a mixture of venoms (chiefly that of the cobra) heated to 80° C. It has not the effect upon all snake-venoms which was claimed by Calmette. Trials on man are full of promise, but ordinary precautions should not be discarded.

Jequirity. Nature—antitoxic. Prepared by treatment with the poison of abrus seeds. It is very effective in laboratory experiments. Calmette suggests its use for controlling the course of jequirity-ophthalmia in ophthalmic practice.

Tubercle. Nature—doubtful. Prepared by treatment with tuberculin or other preparations obtained from tubercle-bacilli. Its practical value is not yet established.

Further a number of other materials—bacterial (staphylococci) and chemical (ricin)—have been made to yield 'anti-serums,' but these are at present only of theoretical and experimental importance. Other preparations, 'antisyphilitic,' 'anticancerous' serums, &c., are at present little better than chimerical.

HERBERT E. DURHAM.

ANTRUM, Diseases of.—See NOSE, Diseases of.

ANURIA.—Absence of urination, whether from suppression or retention of urine. See MICTURITION, Disorders of; and URINE, Suppression of.

ANUS, Diseases of.—The principal affections of this part are:—1. Congenital Abnormalities; 2. Epithelioma; 3. Irritable Sphincter Ani; 4. Irritable Ulcer; 5. Prolapsus; 6. Pruritus; and 7. Tumours and Excrescences. For Fistula in Ano see RECTUM, Diseases of.

1. Congenital Abnormalities (atresia) may be classed as follows:—1. Imperforate anus, without deficiency of the rectum. 2. Imperforate anus, the rectum being partially or wholly deficient. 3. Anus opening into a *cul-de-sac*, the rectum being partially deficient. 4. Imperforate anus in the male, the rectum being partially deficient, and communicating with the urethra or neck of the bladder. 5. Imperforate anus in the female, the rectum being partially deficient, and communicating with the vagina or uterus. 6. Imperforate anus, the rectum being partially deficient and opening externally in an abnormal situation by a narrow outlet. 7. Narrowness of the anus. These imperfections can be remedied, if at all, only by operation.

2. Epithelioma.—The anus, like other parts where a junction takes place between the skin and mucous membrane, is liable to epithelioma. It is easily recognised by the ordinary characters of the sore. Warty growths and flaps of skin at this part are subject to this form of degeneration. The treatment applicable to this disease is to remove the growth by excision.

3. Irritable Sphincter Ani.—In this complaint the anus is strongly contracted and drawn in by the action of the sphincter. Any attempt to examine the part produces spasm, and the finger passed through it is tightly grasped as if girt by a cord. In old-standing cases the muscle becomes hypertrophied, and forms a mass encircling the finger like a thick unyielding ring. This state is the source of serious trouble in defecation, owing to the expulsive power of the bowel being insufficient to overcome the impediment caused by the muscle to the passage of the feces. Irritability of the sphincter, independent of fissure or ulcer, occurs generally in hysterical females, and is relieved by mild laxatives, the local application of cocaine or an opiate ointment, and the occasional passage of a bougie coated with a sedative ointment.

4. Irritable Ulcer.—This is a small superficial sore, situated just within the circle of the sphincter, usually at the back part, commonly known as *fissure*, from its appearance in the contracted state of the part. The feces passing over the sore excite spasm of the muscle, and cause a sharp burning pain which lasts for two or three hours. The distress often does not come on till an interval of ten minutes or more has elapsed after defecation. The pain is sometimes so acute that patients resist an action of the bowels, and allow them to become costive. The irritable ulcer occurs usually in middle life, and is more frequent in women than in men. It seldom gets well under the influence of local applications, but an incision through the centre of the sore sets the muscle at rest, and allows the part to heal. Forcible dilatation of the sphincter with the fingers under an anæsthetic is a very effective mode of treatment. When the suffering is moderate, a cure may be attempted by giving a laxative to ensure soft evacuations, by enjoining rest in the recumbent position, and by the application of an ointment containing morphine, belladonna, or cocaine.

5. Prolapsus.—See RECTUM, Diseases of.

6. Pruritus.—Itching, though a common symptom in disorders of the lower bowel, may occur as a distinct affection, a neurosis liable to paroxysms. It is caused by worms in the rectum, and by congestion of the hæmorrhoidal veins. Patients suffer more after taking stimulating drinks and when heated in bed. The itching is extremely teasing and annoying, especially at night, keeping the sufferer awake for hours. Friction aggravates the mischief, excoriates the skin at the margin of the anus, and causes it to become dry, harsh, and leathery. As regards treatment, stimulants and condiments are to be avoided. The bowels should be regulated, and the part should be washed with soap and water after each evacuation. Every effort should be made to avoid friction. Cotton-wool should be used after defecation in the place of paper. A piece of cotton-wool soaked in oxide of zinc lotion may be kept applied to the anus, or the part may be smeared with some mercurial ointment, such as one of calomel (5j) and vaseline (3j). Lotions of cocaine and glycerine, of borax and morphine, or of carbolic acid are often efficacious. In weak persons quinine and arsenic administered internally help the cure.

7. Tumours and Excrescences.—Besides the flaps and folds of integument consequent on external piles, tumours of a *fibrous* texture sometimes form in the subcutaneous areolar tissue, which as they increase become pedunculated. They are usually small in size, lobulated, and have a firm feel.

These growths may be easily and safely removed by excision. *Papillomata* are liable to be developed around the anus, and sometimes grow so abundantly as to constitute a large cauliflower-like excrescence. They then form projecting processes of various sizes, densely grouped together, with their summits isolated, expanded, and elevated on narrow peduncles. They give rise to a thin, offensive discharge. They probably originate in want of cleanliness. In some persons there is so strong a disposition to the formation of warts, that it is difficult to prevent their growth. They require to be removed by excision, the quickest and most effectual mode of treatment. Flattened growths from the skin, commonly called *mucous tubercles*, a secondary result of syphilis, are liable to occur around the anus. They yield readily to the local application of mercury and general specific treatment. See MUCOUS TUBERCLES.

FREDERICK TREVES.

AORTA, Aneurysm of.—See ABDOMINAL ANEURYSM; and THORACIC ANEURYSM.

AORTA, Congenital Stenosis of.—The commonest seat of this condition is the point of entrance of the ductus arteriosus. There may be complete occlusion, or varying degrees of narrowing of the orifice. The proximal part of the aorta becomes greatly dilated, and the left ventricle hypertrophied. The circulation is carried on by the development of the collateral circulation through the transverse cervical, internal mammary, epigastric, and intercostal arteries, which may become so dilated as to simulate aneurysm, even to the extent of eroding a rib. The most important symptoms are dyspnoea on exertion, cough, hæmoptysis, and cardiac murmurs of various kinds. The condition usually shortens life greatly, but some cases have reached the age of fifty. Death is caused by rupture either of the aorta or of some of the collateral vessels, acute endocarditis, endarteritis, failure of the dilated heart, acute pulmonary complication, or exhaustion.

The aorta may be stenosed throughout and its walls thin, in the condition termed Virchow's Chlorosis (see CHLOROSIS). The aortic orifice may be so small as to scarcely admit the little finger. This hypoplasia, as it really is, is almost invariably associated with a hypoplasia of the generative organs and not seldom with interstitial nephritis. See HEART, Malformation of.

ALEXANDER BRUCE.

AORTA, Dilatation of.—In cases of dilatation of the aorta, there is a more or less uniform enlargement of the vessel affecting most frequently the ascending arch. When it extends into the transverse arch it usually stops short at the origin of the subclavian artery. There is no sharp line of delimitation between simple dilatation and aneurysm. The condition in question is caused by exhaustion of the resisting powers of the wall, and is most frequently associated with sclerosis of the aorta, or with the general rise of blood-pressure which exists in chronic Bright's disease, or in the diffuse sclerosis of smaller arteries. It may also be due to hypertrophy of the heart, whether secondary to any of the above conditions, to aortic valvular disease, or to persistent acceleration of its own action.

Dilatation of the aorta may occur without pre-existing disease of the artery, and, in this case, it

may simply be due to exhaustion, either temporary or permanent, of the elastic fibres of the middle coat. When the dilatation is sufficiently great to produce any physical signs, there is dullness on percussion over the upper part of the sternum, and perhaps also for some small distance to the right of it. There may be palpable pulsation in the episternal notch. In the aortic area a systolic murmur may be heard, while the second sound is generally accentuated or has a booming character. There may be breathlessness, and pain behind the sternum, aggravated on exertion. The dilatation may become lessened or even disappear under rest and other appropriate treatment, or it may remain stationary, or if untreated may even increase so as to deserve the name of aneurysm.

The treatment varies according to the cause of the condition. Rest is required in all cases, and the treatment by diet and drugs will be that of the existing disease, whether Bright's disease, anæmia, vascular excitement, or arterio-sclerosis.

ALEXANDER BRUCE.

AORTIC VALVES, Diseases of.—See HEART, Valves and Orifices, Diseases of.

APERIENTS (*aperio*, I open).—Medicines which produce a gentle action of the bowels. See PURGATIVES.

APHAGIA (*ἀ*, priv. ; and *φάγω*, I eat).—Inability to swallow. See DEGLUTITION, Disorders of.

APHASIA (*ἀ*, priv. ; and *φῆμι* or *φάω*, I speak). SYNON. : Aphemia ; Alalia ; Fr. *Aphasie* ; Ger. *Sprachlosigkeit*.

DESCRIPTION.—Aphasia is the name given to a defect of speech from cerebral disease. The patient is found to be unable to utter any proposition, though his occasional distinct pronunciation of some one or two words shows that his speechless condition is not due to a mere difficulty in the more mechanical act of articulation. Moreover, the patient's intelligent manner and gestures may plainly show that he understands what is said, and is capable of thinking, even though he is quite unable to give expression to his thoughts. This kind of powerlessness as regards speech is most frequently encountered in persons suffering from right hemiplegia, though it is occasionally met with in those who are paralysed on the left side, and at other times in persons who are not hemiplegic at all.

The aphasic condition is not always, as it ought to be, clearly distinguished from that of another group of cases which may be encountered in association with some amount of hemiplegia or independently, and to which the name *amnesia* is given. The essence of this latter defect lies in the fact that the patient's speech is defective because of his inability to recall the proper words for the expression of his thoughts or wishes ; and he very frequently substitutes wrong words or names in the place of those he wishes to employ, as when speaking of his 'hat,' he calls it a 'brush,' or when seeking a 'pen,' he asks for a 'knife.' In a bad case of this kind the patient may be quite unable to arrange words into a sentence capable of conveying a definite meaning, so that his speech is rendered unintelligible. Where this species of defect exists there seems to be either a defective or an inco-ordinate action of one or other of those higher cerebral centres whose function it is to translate

thought into the corresponding motor acts of speech, so that we get hesitation in the utterance of right words, or the substitution occasionally of entirely wrong words or even of a meaningless set of sounds. These amnesic or inco-ordinate defects were not at first recognised as being distinct in nature from those of an aphasic type, in which there is rather a loss than a misdirection of power in one or other of the higher centres whence the incitation to the motor acts of speech proceeds. The two kinds of defects, indeed, not infrequently co-exist to some extent in the same individual.

When occurring in association with hemiplegia, aphasia varies much in intensity according to the degree of general mental impairment with which it may be combined. During the first week or ten days after the onset of such an attack the special defect may be scarcely recognisable, owing to the masking influence of the general mental impairment. But after a time such a patient may regain a considerable amount of general mental power. He may be left more or less hemiplegic, and may also present the aphasic defect to a marked degree. He readily comprehends everything that is said to him, and can often understand what he reads.

But at other times, though able fully to understand when read to, he does not seem to understand when he himself attempts to read—a disability now often spoken of as 'word-blindness.' He can, perhaps, play draughts or chess well, and by means of gestures and pantomime can make his wants and most of his wishes fairly well understood by those accustomed to interpret them. Yet he may only be able to articulate some one or two words, or else combinations of mere unmeaning sounds, such as 'poi, boi, bah,' 'sapon.' On rare occasions, under the influence of strong emotion, the patient may blurt out some simple expletive or short phrase, such as 'oh dear !' He cannot be made to repeat a word, or even the simplest vowel-sound, which he has just heard uttered. In a few cases the patient has seemed unable to understand what is said, as though from some difficulty in realising the meaning of words. Words may have to be uttered very slowly and repeated several times to such a patient, and even then they may fail to convey their meaning—a defect known as 'word-deafness.' Yet the language of gesture, appealing as it does to the sense of sight, may be at once understood.

The patient's power of writing is necessarily interfered with when aphasia, as is so often the case, co-exists with right hemiplegia. Many such patients, however, learn to write with the left hand to a variable extent. The variations as regards the power of writing are, in fact, almost as marked as the variations in power of speaking, though these two classes of defects by no means run parallel with one another in the same individual. The writer has known patients who were quite unable to express themselves in spoken words, or even utter a single articulate sound, write a good letter with no, or very few, mistakes (*aphemia*) ; on the other hand, the performance of an aphasic patient, without a copy before him, may be, and most commonly is, limited to writing his own name. At other times the patient shows an amnesic defect in writing, and writes much as an amnesic patient speaks. Still more rarely it is found that an aphasic patient is, though not from want of manual power, unable to write even a single letter (*agraphia*)—in attempting to do so he makes mere unmeaning strokes.

The disability spoken of above as 'aphemia' may be complete, and then the patient is absolutely speechless. But incomplete aphemia or aphemic defects exist in many degrees of completeness. These terms are now often applied to defects in the power of articulation—the mere mechanical part of speech—in which difficulties exist such as go with diseases in the bulb or the pons, or the slighter defects in utterance, constituting mere 'thickness of speech.' This kind of defect differs from (and may be easily distinguished from) aphasia, seeing that the subjects of it will always attempt at once to utter any word or simple sound, when they are bidden to do so. The term 'anarthria' has been used by some writers for what would be called bad aphemic defects—such, for instance, as are met with in bulbar diseases, where the articulatory motor centres are themselves the seat of lesion.

Aphasia occasionally supervenes, independently of paralysis or convulsions, in individuals who have been subjected to great excitement or prolonged overwork, when it may be due, perhaps, to mere functional derangements. In other cases it presents itself as a temporary condition, lasting only for a few hours or a few days, in a patient who has just had an attack of right-sided unilateral convulsions; or, lastly, as has already been indicated, it occurs in conjunction with a right-sided hemiplegia produced either by brain-softening or by cerebral hæmorrhage. Cases belonging to the latter category vary very much amongst themselves as regards the degree of co-existing hemiplegia. If the third left convolution alone is damaged by softening, the hemiplegic condition may be absent, or transient and incomplete—never, perhaps, affecting the leg appreciably. This condition is often induced by a small hæmorrhage, or by a patch of softening produced by an embolism of that branch of the middle cerebral artery which supplies the third frontal convolution; but where the hæmorrhage is larger, or where the main trunk of the middle cerebral artery is obliterated, either by an embolus or a thrombus, the aphasia, or aphasia with amnesia, is combined with much graver and more persistent hemiplegic symptoms.

PATHOLOGY.—The modern concentration of attention upon these defects of speech was started by the enunciation of Broca's views as to the dependence of the aphasic defects upon lesions in or about the third left frontal convolution. All pathologists are now agreed as to the fact that such lesions are much more prone to give rise to aphasic symptoms than are corresponding lesions on the right side of the brain. It is commonly believed, moreover, that *amnesic* defects of speech are most commonly produced by superficial lesions of the left hemisphere, though by lesions situated farther back—that is, in the neighbourhood of the posterior extremity of the Sylvian fissure.

The third left frontal convolution is not now supposed, as Broca put it, to be the seat of any 'faculty of language,' though the anatomical investigations of Meynert and of Broadbent have shown that its relations with other convolutions are exceptionally complex. Whether certain higher 'motor' centres for speech are situated in this part of the brain, as is commonly believed, or whether such centres are rather, as the writer believes, kinæsthetic centres, it must at least be conceded that this convolution is intimately concerned with the physical expression given to thought in articulate speech.

We know that the left hemisphere is the one from which the volitional incitations proceed in the case of written language, and it is presumed that the same half of the brain also takes the lead in the production of articulate speech. It is, therefore, a point of much interest when we find that, in some of the exceptional cases in which aphasia has occurred in association with lesions on the right side of the brain and left hemiplegia, the individuals had been left-handed during life. Some of the other exceptional cases, however, have not admitted of this interpretation.

Different kinds of Word-memories.—For the proper understanding of these different defects of speech and writing many details are essential. There are four different kinds of word-memory—three essentially different types, but one of them existing in two forms, so as to make four varieties in all. These varieties of verbal memory are as follows: (1) Auditory memory—the memory of the *sounds* of words, that is, of the auditory impressions representative of different words; (2) Visual memory—the memory of the *visual appearances* (printed or written) of words, that is, of the visual impressions corresponding with different words; (3) Kinæsthetic memory—(a) the memory of the different groups of sensory impressions resulting from the movements of the vocal organs during the utterance of words (impressions from muscles, mucous membranes, and skin)—these the writer has proposed to speak of as '*glossokinæsthetic*' impressions; (b) the memory of the different groups of sensory impressions emanating from the muscles, joints, and skin during the act of writing individual letters and words—these the writer has proposed to speak of as '*cheirokinæsthetic*' impressions.

The organic seat of each of these different kinds of word-memory is in relation with its own set of afferent fibres; and the several centres are also connected with one another by commissural fibres, so that the recollection of a word in one or other of these modes doubtless involves some amount of simultaneously revived activity in one or two of the other word-centres. The relative intensity (in the process of recollection of words for ordinary speech) of the memorial revival in each of these centres is probably subject to more or less marked variation in different individuals. In the majority of persons the revival of words in the auditory centre is the most potential process, and that of which such persons are most conscious. In a smaller percentage of persons the revival of words in the visual centre seems to be the most essential process. While in a very much smaller percentage it seems possible that revival in the kinæsthetic speech-centre may be the most conscious process occurring during the recollection of words.

Owing to the fact of the existence of this multiple memory of words, it happens that loss of speech by no means always, or often, implies the loss of the memory of words. Many a patient who cannot speak can yet revive his auditory or his visual memory of words, so as more or less perfectly to understand what he hears, or what he sees (in print or writing), or perhaps what he both hears and sees.

It is also important to bear in mind that for ordinary persons (that is, those who are neither congenitally blind nor congenitally deaf) the four memories of words are mainly called into play in definite couples, namely, the auditory and the glossokinæsthetic revivals taking place in ordinary speech;

and the visual and the cheiro-kinæsthetic revivals taking place during ordinary writing. So that in expressing oneself in spoken words the memories of such words are first principally revived in the auditory centre, and then the nerve-units thus called into activity rouse in immediate succession the corresponding glosso-kinæsthetic elements before the pronunciation of the word can be effected through the aid of the motor centres in the medulla. Similarly, when expressing our thoughts by writing, though the memories of words are probably first revived in the auditory word-centre, like memories are almost simultaneously revived (through the intervention of the audito-visual commissure) in related parts of the visual word-centre; and from this region stimuli must pass through corresponding cheiro-kinæsthetic elements, before the actual writing of the word can be effected through the instrumentality of motor centres in the cervical region of the cord.

There can be no doubt that the functional association existing between the auditory and the glosso-kinæsthetic centres is of the closest kind. But the bond of association between the auditory and the visual centres is no less intimate. These latter centres are often necessarily called into activity in immediately successive units of time. This happens, for instance, in two such common processes as reading aloud and writing from dictation.

In reading aloud the primarily excited visual word-centre must arouse (through the visuo-auditory word-commissure) related parts of the auditory word-centre, since this is the part which ordinarily calls the glosso-kinæsthetic centre into activity, and from it properly co-ordinated incitations issue to call into play the motor-centres in the medulla.

Again, in writing from dictation, the sounds of words reach the auditory word-centre, and the activity thus aroused becomes transmitted (through the audito-visual commissure) to related parts of the visual word-centre, this being the part which usually arouses the cheiro-kinæsthetic centre into activity for the production of writing movements.

In deaf-mutes, in the congenitally blind, and also in certain cases of disease, as it would seem, the relations between the centres are rather those indicated by the dotted lines (*f*, *e*) in fig. 1.

Concerning the Localisation of the different Word-centres.—Looking to the extremely important part that 'words,' either spoken, written, or printed, play in our intellectual life, and to the manner in which they are interwoven with all our thought-processes, it becomes highly probable that most important sections of the auditory and visual perceptive centres are devoted to the reception (and consequently to the revival in thought) of impressions of words; so that, for convenience of reference, we may speak of these sections as auditory and visual 'word-centres' respectively. Similarly, there must be kinæsthetic word-centres of two kinds—the one in relation with speech movements, and the other in relation with writing movements. It is possible that the parts of the general auditory and visual centres which are in relation with word-impressions may be as distinctly defined as are the analogous parts of the general kinæsthetic centres that are in relation with speech movements. Certain it is that there are some varieties of amnesia in which the part of the visual centre in relation with words seems to be specially at fault (causing 'word-blindness'); just as there are other cases in which the

part of the auditory centre in relation with words is either wholly or partially inactive (causing 'word-deafness'), in each case without evident defect in other parts of the general auditory or visual word-centres.

In regard to the visual centre as a whole, it seems to be now established that it is more or less diffused through the occipital lobe. As to the localisation of the general auditory centre, there is some clinico-pathological evidence to show that the auditory word-centre may be in, or in the immediate neighbourhood of, the upper temporal convolution.

The situation of the two kinæsthetic word-centres can, however, be rather more precisely localised. The writer holds the opinion that the so-called cortical 'motor-centres' of Ferrier and others are really sensory centres of kinæsthetic type, by means of which movements are guided (*see* KINÆSTHESIS). That being so, Broca's region, or Ferrier's centre for the movements of the mouth and tongue (*viz.* the posterior part of the third frontal and the inferior part of the anterior ascending frontal convolution), is, in reality, the part of the brain which we have been alluding to as the glosso-kinæsthetic word-centre. The situation of the cheiro-kinæsthetic word-centre cannot, however, be localised with as much confidence, though the strong tendency is to follow Exner, who believes it to be situated in the posterior part of the second frontal convolution.

It must be supposed, therefore, that the auditory and the visual word-centres are situated, the one not far away from, and the other actually within, some part of the cortex of the occipital lobe, and that they are connected together by a double set of commissural fibres (*fig. 1, a, b*). We must also

FIG. 1.—Diagram showing the commissural connections between the different word-centres.

- a.* The visuo-auditory commissure.
- b.* The audito-visual commissure.
- c.* The audito-kinæsthetic commissure.
- d.* The visuo-kinæsthetic commissure.

suppose that two other sets of commissural fibres exist which are of much importance in regard to speech and writing, *viz.* one set (*c*) through which the auditory word-centre acts upon the glosso-kinæsthetic centre, for the production of articulate speech; and the other (*d*) by means of which the visual word-centre acts upon the cheiro-kinæsthetic centre, for the production of writing.

Thus, for speech we have the combined auditory and glosso-kinæsthetic word-centres, acting from the cortex through internuncial fibres, upon motor centres in the medulla; and for writing we have combined visual and cheiro-kinæsthetic word-centres, acting from the cortex through internuncial fibres, upon motor centres in the cervical

region of the cord. In the study of speech-defects generally it is, therefore, needful to consider the effects of lesions: (1) in the different kinds of word-centres; (2) in the different commissures by means of which the centres are connected; (3) in certain internuncial fibres; and (4) in certain motor centres.

Defects of Speech from Lesions in Word-Centres.—According to the writer's views it is not at all needful, as many authorities have thought, to postulate the existence of a separate 'centre for conceptions or ideas.' The supposed theoretical necessity for assuming the existence of some such centre may in most cases be obviated by a fuller recognition of the different degrees of functional excitability that may exist in the auditory and the visual word-centres respectively. It should, in fact, be constantly borne in mind by those who study these defects of speech that each perceptive centre is capable of being called into activity in three modes: (a) by 'voluntary' recall of past impressions, as in an act of recollection; (b) by 'association,' that is by impulses communicated from another centre during some act of perception or during some thought process; (c) by means of external impressions. Now the excitability of these centres is liable to vary much—as a result of advanced age, or of different general or local morbid states. The molecular mobility may be so much lowered that they are only capable of responding to powerful stimuli; in such cases either 'volitional' recall alone, or 'associational' recall as well, may be impossible or more or less difficult, responses occurring only to external impressions—that is, the patients are only able to repeat words pronounced, or to copy words written before them.

The effects of lesions of the different word-centres are as follows: (1) A lesion of the glosso-kinæsthetic centre produces simple aphasia; whilst (2) one of the cheiro-kinæsthetic centre produces simple agraphia. In neither condition is the power of thought very appreciably interfered with. These are commonly supposed to be motor defects, but this the writer believes to be an erroneous interpretation—since they are defects due to the loss of certain sensorial aptitudes (of the kinæsthetic order) just as much as are the other forms of aphasia now about to be mentioned, the existence of which was first pointed out and explained by the writer in 1866, though they were subsequently more prominently explained in 1874 by Wernicke under the name of 'sensory aphasias.' One of these has been known as 'word-deafness' and the other as 'word-blindness.' But defects in the activity of the auditory and of the visual word-centres respectively give rise to varied and complicated results, which can only be very inadequately summarised by these phrases. Thus under the head of (3) lesions of the auditory word-centre, we must refer to totally different defects according to the degree of functional degradation of the centre: (a) slight auditory amnesia from functional defect of the centre, leading to impaired spontaneous speech, owing to forgetfulness of names or nouns; (b) profound auditory amnesia, in which, from similar causes, both voluntary and associational speech are greatly impaired, though imitative speech is retained, and the almost speechless patient may be able to read aloud correctly and fluently; (c) word-deafness and aphasia owing to a destructive lesion of the auditory word-centre, in which the patient is not only unable to comprehend speech, but is himself

speechless, and may also be unable to write spontaneously. Lesions of (4) the visual word-centre, whether functional or structural, reveal themselves in less varied modes; when severe they would result in the production of word-blindness together with agraphia.

Defects of Speech from Lesions of the Commissures between Word-centres.—It seems to the writer better to reserve the word 'commissure' as an appellation for the fibres that connect centres of the like kind, that is, either sensory centres or motor centres; and to name 'internuncial' the fibres which connect sensory with motor centres.

As already stated, double commissures exist between the auditory and the visual word-centres (fig. 1, a, b) which are habitually called into play in certain mental operations, so that their destruction leads to very definite defects. Thus, in naming objects at sight, or in reading aloud, stimuli have to pass from the visual to the auditory word-centre (by the visuo-auditory commissure) before the naming or the reading aloud can occur. Again, in writing from dictation, and probably also in writing any spontaneous effusion, stimuli require to pass between these two centres in an opposite direction, namely, from the auditory to the visual centre, and through a different set of fibres (the audio-visual commissure). In 1880 the writer published (*The Brain as an Organ of Mind*, p. 640) some details concerning a man (who has ever since been under observation from time to time) who suffers from a lesion destroying the commissures in question. This man understands perfectly all that is said to him and all that he reads, yet he cannot read aloud a single word or even name a single letter, though immediately that he hears the word or letter pronounced he can repeat it at once. Again, he cannot write a single word, or even letter, from dictation, though he can at once, with his left hand, proceed to copy any such word or letter that may have been written for him on a sheet of paper. Cases have been recorded also in which the separate halves of the commissure between the auditory and the visual word-centres have been damaged; so that reading from dictation or naming at sight has been interfered with and not writing from dictation, or *vice versa*.

The other commissures whose lesions have to be considered are those (fig. 1, c, d) connecting the auditory with the glosso-kinæsthetic, and the visual with the cheiro-kinæsthetic word-centres. Defects in the course of these commissures are of interest, more especially from the point of view of a regional diagnosis. The writer some years ago pointed out, for instance, that a lesion of any part of the audito-kinæsthetic commissure (fig. 1, c) should produce an aphasia indistinguishable from that which would be produced by damage to Broca's convolution, that is, to the glosso-kinæsthetic centre itself. This is, of course, a very important point, since it shows that it is an error to suppose that typical aphasia can only be caused by a lesion in Broca's region. A precisely similar result should also be produced by complete destruction of the audito-kinæsthetic commissure, in any part of its course between that region and the neighbourhood of the occipital lobe where the auditory word-centre is situated. If the latter centre itself be damaged, as before stated, we then get the aphasia complicated with word-deafness, and thus have the means of arriving at an accurate regional diagnosis. Once clear of the centre, however, a lesion involving any part of the audito-

kinæsthetic commissure should produce a typical aphasia absolutely indistinguishable clinically from that resulting from a lesion in Broca's region itself. This explains the occurrence of aphasia in association with lesions in the island of Reil, and other sites nearer the posterior extremity of the Sylvian fissure (fig. 2, *b*).

FIG. 2.—Diagram showing the possible location of an aphasia-producing lesion, either in the glosso-kinæsthetic centre (*a*), in the audito-kinæsthetic commissure (*b*), or, in association with word-deafness, in the auditory word-centre (*c*).

This point, like the question of the existence and interpretation of aphemia, will be found to be a touchstone for testing the truth of the doctrines here set forth concerning the pathogenesis of speech-defects, as compared with those of Stricker and of Hughlings Jackson. According to their views, the commissural fibres, now referred to, pass between the auditory and a true 'motor' centre for articulation. According to Stricker (*Le Langage et la Musique*, 1885, p. 73), a damage occurring in the course of these fibres would cause not aphasia but word-deafness. His view being that words are realised mainly by memorial revival in motor cortical centres, in the case assumed there would be word-deafness because stimuli could not pass from the auditory to the assumed motor centres in which the essential part of the apperceptive process is carried on. It seems clear also that these doctrines necessitate the view that an isolated lesion in Broca's region only should also cause word-deafness as well as aphasia. This, however, is certainly not the case—a fact which is itself sufficient to negative the truth of the views of Hughlings Jackson and of Stricker.

Damage to any part of the visuo-kinæsthetic commissure (fig. 1, *a*) would also be capable of producing agraphia of just as complete and typical a kind as if the lesion had been in the cheiro-kinæsthetic centre itself.

Defects of Speech from Lesions of Internuncial Fibres.—We have here to do with a kind of defect known as aphemia. This is a speech-defect, and there is no analogous defect of writing, except that which is occasioned by actual paralysis of the right hand. In complete aphemia there is absolute loss of articulate speech without any mental impairment, and with the power of communicating the thoughts by writing preserved absolutely intact. An excellent example has been recorded by the writer in the *Brit. Med. Jour.*, Nov. 5, 1887.

Such a condition is produced when the glosso-kinæsthetic centre is itself uninjured, but where the whole of the internuncial fibres emanating from it and proceeding to the true motor articulatory centres in the bulb are damaged in some part of their

course—whether just beneath the cortical centre, in the internal capsule, in the peduncle, or in the pons. Sometimes the defect may be of a functional rather than of a structural type, constituting Charcot's 'hysterical mutism in the male.'

Incomplete aphemias, however, exist of all degrees of severity, and they are about the commonest of all speech-defects occurring in association with hemiplegia. They are due to partial damage to the group of internuncial fibres above referred to, and are represented by defects of articulation, varying from almost complete unintelligibility to the mere blurred utterance or thickness of speech which is so common.

Aphemia is clearly not a sensory defect—it is not a form of amnesia—because the subjects of it can revive words in all possible modes, and are, therefore, able to think and express their thoughts with an unimpaired freedom by writing. If the aphemia be in any way incomplete, moreover, such a case can be easily discriminated from a case of aphasia by the fact that the aphemic patient will always at once make an attempt, when bidden, to pronounce some simple word or syllable (however poor the attempt may be), while the typical aphasic patient is unable to make any such attempt—he will not try even to repeat the simplest vowel-sound.

Defects of Speech due to Lesions in the Bulbar Articulatory Centres.—In these cases, as where the lesions occur in the internuncial fibres, all the centres in which the memory of words can be revived are intact. There is consequently nothing whatever to interfere with the flow of thought, and in incomplete cases nothing to prevent attempts at articulation being made. These two classes of cases are indeed less separable clinically than they are from a theoretical or scientific point of view.

It would be well to reserve the term 'anarthria,' as introduced by Kussmaul, for the defects of speech caused by morbid states of the bulbar articulatory nuclei—with the full understanding, however, that aphemia and anarthria will often be indistinguishable one from another by their own intrinsic characters, though they will generally be quite capable of being diagnosed one from another by taking into consideration the mode of onset and the particular grouping of other attendant signs.

DIAGNOSIS.—The means of distinguishing the different aphasic and amnesic speech-defects one from another has already been fully enough set forth in the preceding sections. The diagnosis of the exact nature of the defect is often exceedingly difficult, unless the patient be thoroughly examined in a systematic manner, and in accordance with some definite plan. Elsewhere (*Paralyses; Cerebral, Bulbar, and Spinal*, 1886, p. 125) the writer has given such a 'Schema for the Examination of Aphasic and Amnesic Persons,' which has been used with success for many years. The other side of the question, viz. the pathological diagnosis, must be made in accordance with the rules generally applicable to this part of the diagnostic problem in cases of brain-disease.

TREATMENT.—Where aphasia occurs after excitement or overwork, without paralysis, it is a warning of much importance, since it may be the precursor of much graver symptoms. Under such circumstances the patient requires an absolute cessation from work for a time, and most careful watching. Stimulants may need to be diminished;

and bromide of potassium, with sumbul and other sedative remedies, should be administered. Where aphasia is a temporary condition in association with right-sided convulsions, or where it is lasting and co-exists with right-sided paralysis, the treatment of the aphasic condition becomes merged in that of the associated convulsive tendency or paralytic condition, since, as a rule, an amelioration takes place in the patient's power of speaking coincidentally with his improvement in other respects. This, however, is not always the case where aphasia has co-existed with a partial hemiplegic condition: the paralysis may be recovered from, while the aphasic defect may remain more or less as it was. Where this is the case, an attempt should be made to teach the patient to speak again, especially if the defect be of the aphemic type. Such efforts have occasionally been crowned with success, but much judgment and untiring patience have to be called into play in order to obtain satisfactory results.

H. CHARLTON BASTIAN.

APHEMIA (ἀ, neg.; and φημί, I speak).—A term differently applied by different writers, but commonly understood to be a designation for certain articulatory defects (*see* ANARTHRIA) dependent upon injury, direct or indirect, to the internuncial fibres connecting Broca's convolution with the motor centres of the bulb. Where the aphemia is incomplete the nature of the defect is generally obvious; where it is complete the patient is absolutely speechless, and is apt to be loosely described as aphasic, though the fact that he can express himself freely by writing shows that this is not a correct designation of his condition. *See* APHASIA.

APHONIA (ἀ, priv.; and φωνή, the voice). Absence of voice, that is, of intonated utterance. *See* VOICE, Disorders of.

APHRODISIACS (Ἀφροδίτη, Venus).—DEFINITION.—Medicines which increase the sexual appetite and power.

ENUMERATION.—The direct aphrodisiacs include: Nux Vomica and Strychnine, Phosphorus, Cantharides; Quinine; Urtication and Flagellation; Cannabis Indica, Damiana, Opium, and Alcohol in small doses. Iron and bitter tonics; meat-diet; warm clothing, especially around the hips and loins; and abstinence from severe mental and bodily work, act as indirect aphrodisiacs.

ACTION.—Aphrodisiacs may act by increasing the excitability of the nerves passing to or from the genital organs, or of the genital centre in the spinal cord (*see* ANAPHRODISIACS), as, for example, strychnine, nux vomica, and probably phosphorus; by causing irritation of the nerves of the genital or urinary organs or of adjoining parts, as cantharides and urtication; or by stimulating the brain, as Indian hemp or small doses of opium. Alcohol in large doses has a double action, increasing the sexual desire by stimulating the brain, while lessening the power of erection, probably by weakening the nervous mechanism through which erection is produced. As the sexual passion becomes diminished when the nervous system is weakened with the rest of the body, and increases with returning strength, iron with bitter tonics, and generous diet act indirectly as aphrodisiacs.

USES.—When the sexual functions are abnormally depressed, strychnine and phosphorus are the most

generally useful of the direct aphrodisiacs. Cantharides, although sometimes valuable, must be employed with caution.

T. LAUDER BRUNTON.

APHTHÆ (ἀπρω, I inflame).—SYNON.: Aphthous Stomatitis; Fr. *Muguet*; Ger. *Fasch*.

DEFINITION.—A form of catarrh of the buccal mucosa, characterised by the appearance of one or more patches (*aphtæ*) possessing a peculiar structure.

ANATOMICAL CHARACTERS.—Aphthæ have at first the appearance of vesicles; but microscopical sections show that they are due to elevation of the epithelium by a solid fibrinous exudation, over which the epithelium usually dies, soon separating with the fibrinous flake. By the time this is effected the mucosa is again, as a rule, thinly covered by epithelium, so that a true ulcer is never present; but slight suppuration may be established, with the destruction of the superficial layer of the mucosa.

SYMPTOMS, COURSE, AND DURATION.—Aphthæ occur chiefly in children during the first dentition, upon any part of the buccal mucosa—most frequently inside the lower lip and on the tip of the tongue. At first they look like small vesicles, but after a few hours they resemble ulcers with adherent grey or yellowish sloughs, each being surrounded by a ring of injection. The patches vary in size from that of a lentil downwards; they are single or multiple; grouped or scattered; two or three may coalesce, but the patches never reach a large size. Aphthæ cause slight pain, and are especially sensitive to substances like salt or sugar. Dyspeptic troubles are usually present, and the breath is often foul.

Each aphtha runs its course in three or four days, and when multiple the patches come out in a crop. This may be succeeded by other crops, so that all stages of the lesion may be present at one time. The trouble may thus continue for weeks. In other cases patients are liable to crops of aphthæ at varying and sometimes long intervals.

DIAGNOSIS.—Aphthæ have chiefly been mistaken for patches of 'thrush.' Absence of the red areola, and presence of the characteristic fungus, will distinguish thrush even when no history or statement of symptoms can be obtained.

TREATMENT.—The occasional application of a little powdered borax to the aphthæ causes their speedy healing. In prolonged cases, the health in general, and that of the stomach and intestines in particular, must be attended to.

STANLEY BOYD.

APHTHOUS.—A term applied to diseases in which aphthæ are present.

APNEUMATOSIS (ἀ, priv.; and πνεῦμα, respiration).—A synonym for atelectasis. *See* ATELECTASIS.

APNŒA (ἀ, priv.; and πνέω, I breathe).—Apnœa, literally signifying breathlessness, is used by some medical writers as synonymous with asphyxia, the condition which supervenes on suspension or obstruction of the respiratory function. *See* ASPHYXIA.

By physiologists, and with more correctness, the term is employed to signify the cessation of respiratory movements which is brought about by hyper-

oxygenation of the blood; as when an animal is made to inhale oxygen, or to breathe more rapidly than the needs of its economy require.

APOLLINARIS, Waters of.—Acidulous alkaline table-waters. See MINERAL WATERS.

APOPLEXY (ἀπο-πλήσσω, to strike to earth, or disable in mind or body).—The term was at first, and is still, chiefly used to signify sudden abolition of consciousness and power of motion, which, in common English, is also called a *stroke*.

Cerebral hæmorrhage is the most frequent cause of apoplexy; thence 'hæmorrhage into the brain' and 'apoplexy' came to be used as synonymous expressions. Subsequently the effusion of blood itself was spoken of as *the apoplexy*, the word being used to designate the pathological condition causing the symptoms which it at first epitomised. Ultimately it was applied to such spontaneous hæmorrhage elsewhere; and thus extravasations into the substance of the lung, the spleen, or the retina were, and by some writers still are, termed pulmonary, splenic, or retinal 'apoplexies.'

W. R. GOWERS.

APOPLEXY, CEREBRAL.—SYNON. : a 'stroke;' Fr. *Apoplexie*; Ger. *Schlag*. See also APOPLEXY.

DEFINITION.—Loss of consciousness, of voluntary motion, and usually also of evidence of sensation, except that which is afforded by reflex action, coming on more or less suddenly, lasting more than a few minutes, and due to a morbid state of the brain.

The condition of *coma* is termed 'apoplectic' when of sudden or rapid onset. Loss of consciousness may be due to other causes acting directly on the brain, such as defective or excessive supply, or altered condition, of blood; but it is customary to include among the forms of *apoplexy* that only which is due to cerebral hæmorrhage or cerebral congestion, and those which result from distinct toxæmia are sometimes distinguished as apoplectic states. But the word is now seldom used in connection with blood-states, 'coma' being preferred. Unconsciousness resulting from acute anæmia of the brain, or such as attends an epileptic fit, is not termed apoplectic. The term has, of necessity, become restricted, as increasing knowledge has explained the nature of many conditions previously confounded with apoplexy. It should be further observed that the term has always been restricted to such conditions as occur without conspicuous external cause. The same state, when due to an injury, is not called by the name which is employed if there is no injury. The explanation of the inconsistency is to be found in the idea that is to be traced alike in the native and the foreign word. The word 'stroke' has reference to an unseen striker.

The essential cause of apoplexy is thus a sudden cerebral lesion—usually hæmorrhage—occurring without external injury and abolishing for a time the functions of the brain. The same functional state may be caused by obstruction of a vessel by thrombosis or embolism. Profound coma is rarely due to any other spontaneous cerebral lesion. A very small hæmorrhage may cause apoplexy.

Apoplectic symptoms may, however, occur without obvious lesion of the brain. The coma, which is associated with congestion of the head, is sometimes termed 'congestive apoplexy,' and that which occurs in the absence of any recognisable cause has

been called 'simple apoplexy.' This will be referred to presently.

PATHOLOGY.—In all these cases the apoplexy is in relation chiefly to the extent and suddenness of the lesion, and the intensity of the damage. Roughly speaking, its occurrence may be said to depend on the suddenness of the cerebral mischief; its degree on the extent of the same. But the occurrence of apoplexy depends sometimes on the size of the lesion; and the degree varies not only directly with the extent of the mischief, but with the extent of brain-tissue which is exposed indirectly to the irritative influence of the primary lesion. Hence position of lesion has an influence in determining the apoplectic symptoms. For these several reasons apoplexy is especially profound when the hæmorrhage affects both hemispheres, either by simultaneous independent extravasation on each side, or as the result of hæmorrhage into the lateral ventricles, or of hæmorrhage into the pons whence fibres pass to both sides.

The precise condition on which the essential element in apoplexy—the arrest of all manifestation of brain-function—is immediately dependent has been a matter of much dispute. It was formerly ascribed to the pressure exerted by the extravasated blood on the rest of the brain, either influencing directly the cerebral tissue, or pressing on and emptying its capillaries. That such pressure is exerted by a large hæmorrhage is unquestionable. The convolutions on the side of the extravasation are flattened, and the falx is bulged to the opposite side. It cannot be doubted that the intensity of the apoplexy in these cases is due in part to this cause. But this will not explain the occurrence of the symptom in small hæmorrhages, by which no general pressure is exerted, or not more than is at once relieved by the displacement of the mobile fluid which surrounds the vessels. It will not explain symptoms in laceration of the brain, nor the instant loss of consciousness at the very onset of a severe hæmorrhage, in which, as Jaccoud insists, it should, if merely due to pressure, be a late rather than an early symptom. There can be little doubt from these considerations, and from the cases in which there is no recognisable brain-lesion, that what is called shock is an important element in the causation of apoplexy. Thus, in cerebral hæmorrhage the apoplectic symptoms are due in part to the influence on the rest of the brain of the irritation of the nerve-elements by laceration. A hæmorrhage, for instance, stops for a few hours all spinal reflex action by the irritative inhibition downwards, and it stops also the cortical functions by the same process acting upwards. We can thus understand why vascular occlusion causes a slighter degree of apoplexy, since the immediate irritation of the local anæmia is less than that of laceration of the nerve-elements; and also why lesions of the pons produce, as they do, such deep and long-continued coma, since the irritated fibres are connected with a large part of the cortex of both cerebral hemispheres.

Simple apoplexy was a term given by Abercrombie to the cases, once thought to be frequent, in which apoplexy occurs without recognisable brain-mischief or blood-poisoning. Some of these cases were probably instances of uræmic poisoning, and others may have been due to undiscovered and extensive embolism, causing death before there was time for softening to occur. But cases are not infrequent to which neither of these explanations

applies: in which death occurs in an apoplectic form attack, all the organs are found healthy, and the brain only exhibits, in common with the other organs, that passive congestion which results from an asphyxial mode of death. The nature of these cases is still mysterious, but they may be grouped with those in which fatal coma follows an epileptic attack, and is apparently due to the brain-shock produced.

Serous apoplexy is a term formerly applied to cases of fatal apoplexy in which no lesion was discovered except an excess of serum on the surface of the brain. It is now understood that such serous effusion is associated merely with senile atrophy of the brain. There is no reason for associating its presence with the apoplectic symptoms. The cases described under this term were probably instances of uræmia, or of 'simple apoplexy' in old persons with atrophied brains.

SYMPTOMS.—Apoplexy is itself a symptom, and can only claim to be treated as a disease on account of the frequency with which it presents itself as the prominent element in a patient's state. The striking feature of apoplexy is loss of consciousness without failure of the heart's action. The onset is often instantaneous, so that the sufferer falls to the ground. The face may be flushed or pale—it is rarely very pale. The heart and arteries vary in their state; at first the pulse may be feeble from shock, even in cases in which it soon becomes full and tense. Respiration continues, but is laboured and stertorous. The limbs are motionless. In severe cases no reflex action can at first be excited. The pupils may be dilated, contracted, or unchanged: in profound coma they are usually dilated; and they often vary in size spontaneously, and are sluggish in their action to light. The patient can usually swallow, although often with difficulty. The sphincters may permit the escape of urine and feces, or the urine may be retained. In a case of moderate severity the reflex action soon returns, the conjunctivæ become sensitive, the patient can be roused to exhibit response to excitation, and he soon shows returning power of motion. At first there is merely withdrawal of a limb when it is pinched or pricked, but afterwards distinct purposive movements, e.g. opposing disturbance. Afterwards more prolonged and voluntary movements are produced. The patient opens his eyes when spoken to, and tries, when told to do so, to protrude his tongue. On the other hand, the apoplexy may continue or even may deepen in intensity; the respiration assumes the Cheyne-Stokes rhythm, the heart becomes irregular, and the patient dies at the end of a few hours or a few days. Death rarely occurs in a shorter time than two or three hours. In very rare instances an extensive hæmorrhage into the pons or medulla or an effusion of blood into the fourth ventricle may stop the respiration or heart, and kill the patient, in a few minutes.

It is not often, however, that there is this simple loss of cerebral function, uniformly distributed, and gradually deepening or passing away. Much more commonly the symptoms of a local cerebral lesion are added to those of apoplexy. Frequently such symptoms precede the loss of consciousness—unilateral weakness. A unilateral difference may often be recognised during the apoplectic state. The limbs on the one side exhibit more complete muscular relaxation than those on the other; they

fall more helplessly when raised; or there is unilateral rigidity or clonic spasm. Inequality of pupils may be observed, or rotation of the head and conjugate deviation of the eyes. As a patient recovers, these local symptoms become more and more distinct, movement of the face is unequal; one arm is motionless, and the tongue deviates on protrusion.

In *ingravescent* apoplexy the commencement of the cerebral mischief is marked by symptoms of general shock, without any, or with merely transient, loss of consciousness. There is commonly pain in the head, and there may be other localising symptoms. After some hours, during which the patient may continue his occupation, coma gradually comes on and deepens into death. This form of apoplexy, first described by Abercrombie, is usually due to a slowly increasing cerebral hæmorrhage.

The temperature in cerebral apoplexy is at first lowered in most cases, but usually the fall is small, and is succeeded, after twelve to twenty-four hours, by a rise. In some cases there is a considerable rise within the first six hours, and the temperature then commonly continues to rise, reaching 104° or 106° F., and even higher. Such a symptom is a precursor of death.

DIAGNOSIS.—The first diagnostic problem is whether the patient's state comes under the general name of apoplexy; or is one of the morbid conditions in which there is a loss of consciousness, similar in general characters to apoplexy, but due to one of the causes excluded in the definition given above. From the unconsciousness due to cardiac *syncope*, apoplexy is easily distinguished. In the former the heart's action fails, the pulse is weak and imperceptible, the face is very pale, the respiration is sighing and irregular, reflex action is rarely abolished, the sphincters are seldom relaxed, and the patient soon revives.

From the several forms of *toxæmia* the diagnosis is often easy, sometimes extremely difficult. It is easy when, on the one hand, the symptoms of apoplexy are preceded or accompanied by those of a local cerebral lesion; or when, on the other hand, the direct or circumstantial evidence of poisoning is clear, or the symptoms of toxæmia unmistakable. Where there are no local symptoms, and where no guiding history is to be obtained, the diagnosis is difficult, but a correct opinion may commonly be formed by an attentive comparison of the symptoms present.

There may be, as just observed, indirect evidence of toxæmia: the breath may smell of opium or alcohol; the urine may contain albumen. But albuminuria or a smell of spirit may mislead. Cerebral hæmorrhage often occurs after drinking; spirit is usually given to a person who loses consciousness. A smell of spirit must therefore only be allowed weight in the absence of any evidence of cerebral mischief. So, too, albumen is always present in the urine in uræmia, but it is also very frequently present in cases of cerebral hæmorrhage. Alone, this evidence of Bright's disease is of little value, except there be general œdema and the patient be young; then uræmia is more probable than cerebral hæmorrhage. The urine should always be examined microscopically for evidence of structural changes in the kidneys. But with other symptoms which suggest uræmic poisoning, albuminuria is conclusive.

The age of the patient should be considered. Late life is in favour of brain-disease. The history of a fall or a blow on the head adds weight to other symptoms of cerebral mischief.

The character of the coma will sometimes guide us. In uræmia, and commonly in alcoholism, it is less profound than in cerebral mischief, so that the patient can readily be roused. In apoplexy, in opium-poisoning, and in the most intense form of alcoholic poisoning, the coma may be profound. On the other hand, in cerebral hæmorrhage the patient may sometimes be roused to answer questions. Violent struggling is strongly in favour of drink.

The mode of onset of the coma is important. In apoplexy it is sudden; in uræmia it is slow. The uræmic patient becomes first drowsy, then comatose. But with convulsions uræmic coma may come on suddenly. The onset of the coma of opium- and alcohol-poisoning is also slow. In-gravescent apoplexy is of deliberate onset, but a profound degree of coma is quickly reached.

General convulsions at the onset exclude drunkenness, and usually opium-poisoning, while they favour the probability of uræmia, especially if they are followed by rigidity that changes its seat. When uræmic convulsions begin locally, the place at which they begin often varies. Cerebral mischief sometimes commences with a convulsion, but the convulsion is then commonly unilateral, at least in onset, and the preponderant affection of one side at a time is indicated by the deviation of the head. It is seldom that well-marked deviation of the head and eyes occurs, first to one side and then to the other, as the fit progresses, unless there is an organic lesion of the brain, and one-sided symptoms are almost always to be recognised afterwards. Rigidity of limbs or local muscular twitching during the coma is, if constant in seat, in favour of cerebral mischief; if variable in position, it is in favour of uræmia (Reynolds). In diabetic coma, the odour of the breath, and the result of an examination of the urine (never to be omitted) will prevent mistake, even in the absence of a history of diabetes. But the absence of local cerebral symptoms must be carefully noted, since the presence of diabetes does not exclude a cerebral lesion. Post-epileptic coma is of course preceded by a convulsion, and should be borne in mind. In all cases the state of the limbs on the two sides should be carefully observed. When there is brain-disease it is common to have some movement on one side, and great flaccidity on the other. There is often also a difference in reflex action and in the effect of sensory stimulation of the skin.

The state of the pupils alone is of little importance. Great contraction occurs in and suggests opium-poisoning, but it is present in hæmorrhage into the pons Varolii. The pupils may be either normal or dilated in uræmia, in alcoholic or in belladonna-poisoning, and in apoplexy. Inequality of pupils, a unilateral symptom, points to brain-mischief. The retina should be examined, since the presence of albuminuric retinitis points, in the absence of the signs of a localised cerebral lesion, strongly to uræmia.

Lastly, the temperature should be noted. In uræmia there is persistent uniform depression; in cerebral lesions the initial depression is succeeded by a rise to a point above the normal.

The second problem in diagnosis is the precise

cause of the apoplexy, the existence of which has been ascertained by the considerations just reviewed. This element, however, will be described more fully under the heads of the chief lesions that produce the state—cerebral congestion, hæmorrhage, and softening. It may be here pointed out that slight and transient apoplexy, without local symptoms, with flushed face, and coming on during effort, points to cerebral congestion; slight and transient apoplexy with marked local symptoms points to softening; early and profound loss of consciousness to cerebral hæmorrhage. Post-epileptic coma may be distinguished by the history of epileptic attacks; or, if this be not forthcoming, it may be suspected if symptoms of a local cerebral lesion or indications of toxæmia are absent, if the patient be under forty, and exhibits indications of speedy recovery, and also if he has bitten his tongue and passed urine. 'Simple apoplexy' cannot be diagnosed during life, since freedom from the symptoms of a local lesion does not afford ground for inferring that there is no such lesion.

PROGNOSIS.—The prognosis in cerebral apoplexy depends in part upon the intensity of the attack. As long as unconsciousness is complete, and reflex action abolished, the patient is in danger of speedy death. The longer the apoplectic condition lasts without improvement, the less prospect is there of recovery. Persistent depression of temperature, or a rise of several degrees above the normal either with or without an initial fall, is of grave significance; such cases rarely recover (Charcot, Bourneville).

The nature, extent, and position of the cerebral lesion, when they can be inferred, furnish other prognostic indications. In hæmorrhage the prognosis is more serious than in softening. A sudden occurrence or increase of apoplectic symptoms, a few hours or days after a slighter attack, is always grave, indicating a fresh extravasation. If such apoplectic symptoms become profound and uniform, the prognosis is fatal, rupture into the ventricles or on the surface of the brain having probably occurred. If the localising symptoms point to a lesion of the medulla or pons, the prognosis is almost as unfavourable. Early return of consciousness and slightness of alteration in temperature are favourable signs. Previous cerebral disease renders the prognosis worse. Lastly, the prognosis must be influenced unfavourably by any impairment of the organic functions of circulation and respiration, whether independent of or due to the cerebral lesion. Previous alcoholism, from its effect on the nutrition of all tissues, is especially serious.

TREATMENT.—The treatment of cerebral apoplexy must be guided by the indications of its cause. Where none can be obtained, it should be treated by a system that is a compromise. The chief causes are hæmorrhage and thrombotic softening of the brain. Embolism seldom causes pronounced apoplexy. The measures therefore must be such as are suitable to both states, those being excluded which, while they would do good in one, would do harm in the other. But such a compromise is seldom needed. Diagnostic indications can usually be traced with clearness, and as a rule also several coincide distinctly in this direction, while those that do not point in this direction are neutral. Hence, as a matter of fact, there should seldom be the hesitation that interferes with the proper energy of treatment. Stillness is the most important con-

dition. The patient should be moved as little as possible, but placed in the recumbent posture with the head slightly raised. The neck should be freed from constriction. If the extremities are cold, warmth may be applied to them; and cold to the head if there is local heat or flushing. Sinapisms to the neck and extremities sometimes seem to hasten the return of consciousness. The administration of stimulants should be regulated by the state of the heart. In thrombosis or embolism, with signs of cardiac weakness, the heart should be kept up to the normal by very careful administration of alcohol, ether, or ammonia. In hæmorrhage it may be allowed to fall a little below the normal, but indications of failing power should be watched for and counteracted. Where no causal indications exist, the latter is the wiser plan. Venesection and purgation are remedies of similar effect, but different in degree, and are indicated by high arterial tension and cephalic congestion, shown by incompressibility of the pulse and flushing of the face. Venesection is useful where the heart acts strongly, and the pulse is full as well as incompressible. Its effect is proportioned to the rapidity with which the blood is taken, rather than to the quantity removed. Purgatives remove serum from the blood, and lessen the amount of blood within the skull by causing an afflux to the capacious intestinal vessels. The best purgative is croton oil or calomel. With a failing heart and pale surface they should be avoided. When in doubt we should give a mild aperient that acts quickly, such as senna or a little solid extract of cascara rubbed up in water, and the action should be ensured by a glycerine enema. Diuretics may always be used to relieve the vascular tension. As the apoplexy clears, the nature of the case becomes evident, and the treatment of the several conditions is described elsewhere (*see* BRAIN, Hæmorrhage into, and BRAIN, Softening of). For treatment of the other causes of the apoplectic state, *see* ALCOHOLISM, POISONS, and URÆMIA. W. R. GOWERS.

APPENDIX VERMIFORMIS, Inflammation of.—SYNON. : Appendicitis; Epityphlitis.

DEFINITION.—A large proportion of cases of this disease tend to involve the peritoneum locally (*perityphlitis*) or generally, so that the name *appendicitis* has come clinically to have a wider range of application than mere inflammation of the appendix vermiformis, and to include peritonitis starting from the appendix. Indeed, appendicitis apart from peritonitis can scarcely be said to occur clinically.

ÆTIOLOGY AND PATHOLOGY.—Inflammation of the appendix conforms in its anatomical characters to the general features exhibited by this morbid process in mucous membranes elsewhere. Various forms such as 'catarrhal' and 'suppurative' are described, but the interest lies rather with the causes, both predisposing and exciting, which lead to these states, and with the results which follow on their becoming established.

There is little doubt but that the essential cause is *microbic infection*, and it is most probable that the *Bacillus coli communis* is the organism that, in the majority of cases, brings about the disease (*see* B. COLI COMMUNIS). Other microbes, such as *Staphylococcus pyogenes aureus*, *Streptococcus pyogenes*, and *Diplococcus pneumoniae*, have been met with in association with the B. coli, and, in very rare cases, have been the only organisms found. It would

seem that the B. coli, which is a constant inhabitant of the intestines in health, may take on virulent characters; and it is possible that the presence of the cocci contributes to this end, as also may other conditions existing in the canal which are to be regarded as predisposing causes. Among these latter is the presence in the appendix of foreign bodies which are only very occasionally derived from the ingesta—such as stones or seeds of fruit—but which far more commonly consist of fecal concretions having for a nucleus masses of bacteria, and often simulating vegetable seeds in their appearance. The irritation of these substances impacted more or less firmly in the appendix may be the starting point of the inflammation.

Most cases of appendicitis are to be attributed to some morbid condition of the alimentary canal. One of the commonest precursors of an attack is a large and indigestible meal, taken perhaps when in a state of fatigue after a long abstinence, or when in a condition of mental depression or excitement. The result is that a considerable portion of the food escapes gastric and intestinal digestion, and may be found scarcely altered in the cæcum. Constipation is also a very frequent cause, and it is supposed that this state assists in increasing the virulence of the B. coli. An inadequate emptying of the cæcum and appendix is immediately responsible for a large proportion of the cases. Increased and irregular peristalsis extending into the appendix may easily render any existing concretion more dangerous; and the appendix may also be involved in the extension of any neighbouring inflammation, ulceration, or new-growth, as for example actinomycosis or tubercular ulceration. Similar conditions may of course originate in the appendix itself. That appendicitis is often due to disease of the right ovary or Fallopian tube is undoubted, and the communication known to exist between the lymphatics of these several structures probably explains the fact. Whether the ovary may be secondarily affected from the appendix is not so certain.

Direct injury to the appendix is sometimes, though very rarely, the sole cause, but it may light up a morbid state already in existence. Kinks or twists of the organ are occasionally the origin, and these owe their occurrence to differences in the length and position of the appendix and to the extent of the mesentery which it possesses. If the lumen be thus occluded, the secretions are retained and swelling of the distal part takes place, thereby favouring the growth and diffusion of any organisms present, as well as impeding the blood-supply.

Certain other anatomical features are regarded as predisposing causes. Thus the fact that the appendix is an obsolete structure is supposed to favour the incidence of inflammation; while the large amount of lymphoid tissue contained in its walls has suggested a comparison with the tonsils, and to some has justified the existence of a 'rheumatic appendicitis'—an assumption that will much depend upon the view taken as to the nature of 'rheumatism.' The occasional association of arthritis with appendicitis has also been regarded as supporting a 'rheumatic' origin for some cases. However this may be, it is certain that those cases in which 'chill' appears to be the provoking factor are often very completely relieved by salicylate of sodium. Again, a difference in the arterial supply of the two sexes has been noted, and may seem, in part, to explain the greater proportion

of cases among males, in whom there is but one arterial branch, while in females an additional twig is derived from the ovarian artery, an arrangement which diminishes the chance of gangrene. Of still greater importance is the discovery that the sub-mucous tissue is continuous with the subserous tissue through intervals in the muscular layers, a disposition which obviously facilitates the extension of an inflammation of the mucosa to the peritoneal coat.

It is significant that the *results of experiments* designed to set up appendicitis in animals (rabbits) tend to confirm the relative insignificance of foreign bodies as a cause of the disease, and the preponderant importance of blocking of the lumen of the organ in increasing the virulence of the contained organisms—a result which, together with the impaired resistance of the tissues, is aggravated by the impeded blood-supply consequent on twisting of the organ with compression of the vessels.

Nearly three-quarters of the cases occur between the ages of ten and thirty, and more than half before the age of twenty, but the disease has been met with in children three years old, and as late in life as eighty. Statistics show the disease to be more prevalent in summer and in hot climates.

MORBID ANATOMY.—As regards the morbid changes met with in the appendix great variety is to be seen. In those cases which run an acute course, the earliest conditions may require a microscopic examination for their detection, and an appendix that exhibits no naked-eye appearances of disease is not therefore on that account to be considered as healthy. In such cases a simple catarrh of the mucosa is found with proliferation of the epithelium, an excessive mucous secretion, and innumerable micro-organisms of the varieties mentioned—all filling up the lumen of the appendix. Minute ulcerations of the mucosa may be detected, and an invasion of the submucosa by the organisms. In a number of cases the change may be limited to this, and many of those which recover may be of this character, but the possibility of extension to the peritoneum is apparent. In other cases suppuration develops in the wall of the organ, being determined by the invasion of micro-organisms through the damaged mucous membrane. Extension to the peritoneum takes place and a local peritonitis is set up, but the liability for this to become general is obvious. In other cases, ulceration of the mucosa, extending through the thickness of the wall, leads to perforation and escape of the appendicular contents, with subsequent general septic peritonitis, unless this be limited by adhesions. In the worst cases the appendix may rapidly become wholly or in part gangrenous, and in that way lead to peritonitis. It is the occurrence of general peritonitis that confers the grave character on this disease, and this complication is clearly liable to ensue in any case, however mild the initial process may be.

An *appendicular abscess* is primarily intraperitoneal, and is an encysted form of suppurative peritonitis. In the majority of instances the centre of the abscess is behind the cæcum. The contained pus is very rarely of wholesome appearance and free from offensive odour. In the large majority of the cases, however, it has a distinctly fecal smell, a circumstance which attends most abscesses in connection with the lower bowel, and which does not of necessity imply that the contents of the intestine have escaped into the abscess-cavity. In the

minority of the examples the abscess does contain fecal matter, and the lumen of the intestinal canal is opened up. The fecal material may have escaped through a rent in the appendix, or may have followed gangrene of that process, or, less often, may have made its way through an aperture in the cæcum. This perforation may have proceeded from within outwards, but more usually it is due to the bursting into the cæcum of an abscess which had commenced outside the caput coli. The direction in which the abscess tends to burst is illustrated by sixty-seven cases collected by Bull. In twenty-eight instances it burst through the anterior abdominal parietes; in fifteen it entered the cæcum; in eight the general peritoneal cavity; and in two instances each it made its way respectively into the thorax, the rectum, and the bladder. The abscess often shows a tendency to extend upwards behind or along the ascending colon, and it is by this route that the thorax has been reached and an empyema produced. The abscess, when it extends to the pelvis, may pursue the course of any other pelvic abscess, and may thus make its way out into the buttock and perinæum, and may even extend down the thigh. The comparative frequency with which a suppurative collection, started by disease in the appendix, may make its way into the cæcum has given rise to an exaggerated and erroneous idea of the frequency with which the cæcum is primarily involved in these cases. Suppurative pylephlebitis may be met with in association with perityphlitis.

As a sequence of repeated attacks of inflammation, the lumen of the appendix may become obliterated and its walls converted into tissue of tedious hardness. In these chronic cases, the organ may be embedded in dense fibrous tissue, the result of a progressive adhesive peritonitis.

SYMPTOMS AND COURSE.—The signs and symptoms which are associated with the structural changes just described, and determined by the causes just indicated, exhibit a marked variety in mode of onset, course, severity, and duration; so much so that descriptions of extreme cases are scarcely recognisable at first as pertaining to what we regard as the same disease. The exact relation of the clinical phenomena observed to the existing anatomical changes is sometimes uncertain, more especially in the milder cases which end in complete recovery, and cannot be investigated *post mortem*. Cases of severe pain over the right iliac fossa, the point of greatest intensity and tenderness being midway between the umbilicus and the right anterior superior iliac spine but without any recognisable physical signs, have been termed 'appendicular colic'—an unfortunate phrase, since there is no reason to suppose that their cause is a painful muscular contraction, though there are good grounds on the other hand for believing that such symptoms are associated with the early structural changes above described.

Three other well-marked groups may be recognised, to one or other of which most cases may be referred, though occasionally the disease runs a course which cannot be exactly included within any one of these types.

(a) In the first group will be found those cases which, occurring in apparently healthy persons, or with but very little and unimportant previous symptoms, run an exceedingly rapid course of a few hours, death resulting at the outside within two days. Here the symptoms are mainly those of

perforation of the intestine, with very little indication of the seat of the lesion. The patient is suddenly attacked with severe abdominal pain, by no means necessarily felt in the neighbourhood of the cæcum, but often about the umbilicus, followed by all the symptoms of collapse, which may be very soon fatal (*see* INTESTINES, Perforation and Rupture of). The necropsy reveals perforation of the vermiform appendix or gangrene of that organ and more or less diffused peritoneal inflammation. Intestinal toxæmia with rapid loss of strength and often marked vomiting are features of this variety.

(b) The onset of the symptoms in the next group also takes place as a rule without any history of previous discomfort, constipation, or illness; and while less rapid than in the preceding, they are usually well marked. Often commencing with a chill or rigor, these cases are also characterised by acute pain, indifferently referred to the belly generally, or perhaps specially to the umbilical or cæcal region. The pain may cause a moderate degree of collapse, but not nearly so severe as that associated with acute perforation, which we may surmise in the cases under consideration has not yet actually taken place; or if it have occurred its effects are strictly confined to the immediately adjacent region. With the pain, which becomes paroxysmal and often radiating to the testis, pudendum, thigh, or bladder, there is considerable tenderness, which may be distinctly limited to the right iliac region and most marked at the point previously mentioned, and thereby becomes an important factor in the diagnosis. Other signs of localised peritonitis quickly supervene: the abdomen becomes distended and tympanitic; and a slightly increased resistance is perceptible over the cæcum, due in part to the rigidity of the abdominal muscles, and partly perhaps to retained feces in the cæcum, or inflammatory effusion around that structure. The temperature rises two or three degrees, or even to 104° or 105° F.; the pulse is frequent and thready; respirations are quickened; and the aspect of the patient is that of severe illness. There is constipation; often severe tenesmus; and vomiting, which may be mild and only excited by food, or of a bilious character, but its occurrence is not followed by any sensation of relief. The tongue is thickly coated, or dry brown and cracked, with sordes on the teeth. Some observers have noted a very abundant flow of urine, containing an excess of indican; and frequency of micturition. The patient may remain in much the same state for two or three days, when the pain and tenderness spread over the abdomen. The legs are drawn up and the arms raised above the head so as to relax the parietes and increase the capacity of the abdominal cavity; and with an intensification of the above symptoms there exist all the evidences of general peritonitis, from which the patient may succumb within the next few days, though recovery even at this stage is not quite unknown. Or the inflammation may assume a distinctly suppurative character, leading to the formation of a large quantity of pus encysted within the peritoneal cavity in the cæcal region, giving rise to an increasing fulness and resistance, which may be detected through the abdominal wall, or sometimes by rectal or vaginal examination. The abscess thus formed may extend, and burst in one or other of the directions already indicated. On the abdomen being opened, either by the surgeon or *post mortem*, the mischief is seen to have started from ulceration and perforation of the appen-

dix; and these cases only differ from those in the former group in degree of severity and rapidity, their longer duration affording the opportunity for the development of additional symptoms. It may be observed that cases of this severe type do occasionally begin with mild symptoms such as characterise the following group, or the graver manifestations may be delayed in their occurrence; but it is estimated that 68 per cent. of the fatal cases die within eight days.

(c) The third class of cases—certainly the most numerous—include those which are much less severe in their character, more prolonged in duration, and generally recover. Contrary to what obtains in the previous groups, the patients are more frequently women, and a previous history of constipation or of ovarian trouble is the general rule. After perhaps a more than usually obstinate confinement of the bowels, or some gross error in diet, such as eating a very large quantity of nuts, the patient complains of very definite pain over the cæcum, which is found to be tender, swollen, resistant, and dull on percussion, due to fecal accumulation. It is the prominence of the local symptoms which specially characterises this class of cases, the seat of the trouble being obvious from the commencement. There is also a moderate and very irregular rise of temperature, rarely exceeding 103° F., with soft quick pulse, and general febrile symptoms. The constipation persists, owing to the arrested peristalsis from inflammation of the bowels; and nausea or vomiting is of frequent occurrence, though not often very severe. It is in these patients that is commonly noticed the drawing-up of the right leg, which is flexed across the other thigh, so as to relieve as far as possible the pressure of the abdominal wall on the swollen region. The pain continues of a dull aching character, now and then with sharper twinges, and often spreads across the lower part of the abdomen, and suggests an extension of the peritonitis, though it is doubtful whether this is really the case; it also shows a great tendency to pass down the inner and anterior surface of the right thigh, due to pressure on the genitocrural nerve. Sometimes there is oedema of the right leg, from thrombosis of the iliac vein induced by pressure. The duration of these cases is very uncertain, and much depends on their treatment; some last but a few days, others may continue for two or even three weeks, varying much in the severity of the symptoms, for some days the patient being gravely ill and then appearing considerably better, fluctuating from day to day. The extent of the swelling and dullness is frequently changing, as also to a less degree the pain and general symptoms. A small proportion of the cases which run the course described end in suppuration, and the formation of a circumscribed abscess, such as occurs in the former group; but the greater majority end in resolution. How far the appendix is concerned in these cases is doubtful, and certainly it is unlikely that gross lesions of that structure occur in any but the few which suppurate. It is probable also that in certain of the milder cases the cæcum is more at fault, being in a state of inflammation and probable ulceration, determined by the irritation of the hardened feces, and that it is a true typhlitis—the *stercoral typhlitis* of writers—the well-defined swelling being partly formed by the thickened wall of the inflamed bowel, with perhaps some peritonitis (perityphlitis), and still more by the retained intestinal contents.

Relapsing appendicitis.—A marked characteristic of the morbid state under consideration is its liability to relapse—40 per cent. of the cases are estimated to do so. A slight indiscretion in diet may be sufficient to re-induce it, and it may recur from this cause again and again; or it may be that the patient has got about before the attack has completely subsided; or in many cases relapse may occur when every care has been taken, and successive recurrences are likely to be of increasing severity. In women attacks are often coincident with the 'period.' When suppuration has taken place as a result of perforation of the appendix and escape of the original irritant, concretion, or foreign body in the discharge from the abscess, recurrence is not likely to happen; but so long as it remains it is an ever-present source of danger: there will be no relapses if the appendix have become gangrenous and separate. The exciting causes of these relapses may be found in the condition of the appendix itself, which by becoming twisted or bent on itself, fixed by adhesion, or stenosed by a cicatrix of an old ulcer, permits an accumulation of mucus within it, and consequent distension of its distal end; this condition is sufficient to set up a localised peritonitis, which recurs until the pseudo-cyst is emptied, and the lumen of the process finally and completely occluded. The attacks which form the third group of cases above described, which are closely associated with fecal retention, are also likely to be repeated unless the bowels are kept regularly and thoroughly opened. The liability to some accumulation taking place, even when there is a daily evacuation, is not to be forgotten. It is very common to find that the subjects of relapsing appendicitis have imperfect teeth or bolt their food.

DIAGNOSIS.—The condition known as appendicitis requires to be distinguished from several other intestinal affections. In ileo-cæcal invagination, which may give rise to many of the symptoms above described, the evidences of obstruction rather than of peritonitis predominate, the pain is more acute, and vomiting is usually more severe and persistent, while the stools contain bloody mucus; tenesmus also in these cases is much more marked. Other forms of acute intestinal obstruction may be mistaken for it, and often cannot be distinguished; the presence of distinct swelling, dulness, tenderness, and pain restricted to an area in the iliac fossa are of primary importance in determining the case to be appendicular. In appendicitis the temperature is raised, in acute obstruction it is usually lowered. Occasional cases of enteric fever, where there are constipation and absence of rash, may be confused with the malady under consideration, especially as the neighbourhood of the cæcum is the situation where the most distinct signs occur in both diseases; but the history, the course of the fever, and the characteristic tongue and general appearance of the patient in typhoid fever, together with the sequence of headache and delirium and splenic enlargement, should afford grounds for discrimination. Less often may tubercular peritonitis need to be separated, but here again the history, temperature, and coincidence of other evidences of tuberculosis elsewhere must be considered. Suppuration in connection with the ovary, or behind the peritoneum from caries of bone or perinephritic abscess, may simulate the fecal abscess following appendicitis.

PROGNOSIS.—Owing to the liability of even the mildest case to become severe, appendicitis should

always be regarded as serious and the prognosis as uncertain. The general mortality of all types taken collectively is probably 5 per cent., but while the simplest (group 3) are very rarely fatal, of the really fulminant cases at least 80 per cent. die; while among those cases in which suppuration occurs and an abscess is formed, a mortality of about 30 per cent. occurs.

The forecast in any single case is concerned with the immediate recovery, and the liability to relapse.

As regards recovery, this will obviously depend on the stage at which the case is seen and the previous duration of it, as well as the particular form which the malady has assumed. The general basis of prognosis in this respect may be inferred from the figures just given.

Much difference of opinion, due to absence of sufficient information, is held as to the likelihood of relapse in a case in which there has been but one attack. It is probable that a relapse occurs in 40 per cent. of the cases, the recurring symptoms exhibiting all degrees of severity from a more or less constant slight pain over the cæcal region with local tenderness, discomfort on much movement, perhaps occasional vomiting and constipation, to a definitely acute attack. Such a recurrence may be repeated again and again. It cannot be said that recurrent attacks are less dangerous than the first; patients have survived ten attacks and have died of the eleventh.

As to the necessity for operation very opposite views are held. While few would dispute the propriety of laparotomy where there is reason to suppose perforation has occurred or gangrene has set in, i.e. in the severest cases, unless the patient be actually moribund; or the need for opening the abdomen if suppuration has developed and an abscess has formed; much difference of opinion and of practice exists as to the proper treatment of the mild cases. At one extreme are those who would remove the appendix at the first evidence of trouble, at the other are those, relying on the great probability of recovery and taking the chances as to relapse, who would counsel reliance on the expectant treatment. Between such views it is difficult to take a middle course, and the practical question resolves itself into what are the indications of pus-formation which may occur in any case and should necessitate operation. Some help on this point may be gained from the general condition of the patient, which may be gradually getting worse, with possibly, but by no means necessarily, a further rise of temperature, perhaps a rigor; in some cases an increase in pain and tenderness, in others not so; a hurried respiration and a brown tongue with a tendency to restlessness and progressive sense of illness; an increase in the local swelling and area of dulness with increased tenderness. However suggestive such indications may be collectively, individually they have but little value, since pus may develop in the most opposite conditions of their occurrence. A more reliable sign is the rate and quality of the pulse. It may be simply affirmed that an increase in the frequency of the pulse beyond 120, or much above what it had hitherto been, points to suppuration, provided the increase be not due to any temporary excitement or disturbance.

Complications such as pyelephlebitis and pyæmia, or the supervention of pneumonia or other lung-complication; or the exceptional occurrence of uncontrollable diarrhoea and vomiting will necessarily add to the gravity of the prognosis.

The common causes of death are collapse, septic intoxication, the effects of suppuration, pneumonia, pyelophlebitis, pyæmia, and such accidents as hæmorrhage.

TREATMENT.—This must obviously differ very considerably according to the severity of the case, and may conveniently be considered according as operative interference is or is not called for.

When the disease is distinctly associated with fecal impaction, and when the symptoms are milder and somewhat more prolonged in duration, recovery is to be expected without operation, although, as stated, occasionally an abscess forms, which may require to be opened. For such patients as would be included within the third of the above-described groups, rest is essential, and the treatment consists in a judicious application of means to remove the contents of the cæcum, together with such an amount of sedative as will serve to keep the parts concerned as quiet as is consistent with the necessary evacuation. To meet the first indication enemata of plain water or soap and water are the most satisfactory. They should not be too large—fifteen to twenty ounces for an adult—and should be repeated, but not too frequently; it is rarely desirable for the enema to be given more than once in the day, and every other day is usually often enough. Much harm may be done by inducing a violent evacuation, though there may be a large quantity to be removed, and it is far better for this to be effected gradually. Some advise, in addition, frequent small doses—twenty grains—of sulphate of magnesium or sodium, not with a view of direct purgation, but to induce a moderate intestinal secretion, whereby the hardened feces may be somewhat softened. Anything in the nature of a violent aperient is strongly to be deprecated, and it is better to give occasional doses of opium, gr. $\frac{1}{4}$ to $\frac{1}{2}$, by the mouth, whereby pain is relieved and the risk of peritonitis appears to be diminished. For the same object, three or four leeches applied over the cæcum are most effective; or hot fomentations, either made with poppy-heads or applied after the surface of the abdomen has been painted with extract of belladonna and glycerine. The diet should be restricted in amount as much as possible; there is usually anorexia, and abstinence from food is beneficial; occasional teaspoonfuls of hot water or hot weak tea, and a few ounces of peptonised food are amply sufficient as a rule, and stimulants are very rarely needed. It cannot be too strongly insisted upon that the patient should be kept in bed, even for some days after complete cessation of all symptoms, as a very little exertion or slight excess of food may be sufficient to induce a relapse.

If the symptoms persist, if the temperature keep high and the pulse increase in frequency, and if the local phenomena become more prominent, then an incision over the swelling will be called for. It is seldom until after the fifth day that surgical interference is demanded. In the cases dealt with by the surgeon the dulness will have increased, the local tenderness will be more marked, and possibly redness of the skin and oedema may indicate the importance of immediate treatment.

The treatment of cases of the first group is identical with that followed in instances of acute perforative peritonitis. A prompt abdominal section carried out without a moment's delay offers practically the only prospect of saving life.

In dealing with cases of the second group, the general measures already described are employed. If the local and general symptoms persist, an incision will be called for. This, as already stated, is seldom indicated before the fifth day.

In cases of relapsing appendicitis the operation for the removal of the appendix is called for when the attacks are severe or are increasing in severity, when the attacks are becoming numerous, when the last attack has been of an alarming character, or when the repeated illnesses to which the patient is rendered liable are undermining his health, or interfering with the pursuit of his calling or his enjoyment of life.

In any case in which this operation is undertaken it may be assumed that the enlarged appendix can be made out after the acute symptoms have subsided. The removal of the offending appendix should be carried out during the period of quiescence, and after all the usual symptoms of appendicitis have disappeared.

It has been shown that the danger of the operation is less than that attending another attack.

W. H. ALLCHIN. FREDERICK TREVES.

APPETITE. Disorders of.—In disease the desire for food may be either *lessened* or *increased*; or the appetite may be *perverted*, and a longing for various substances unfitted for or incapable of digestion may be displayed.

Loss of appetite—*Anorexia* accompanies fevers, almost all forms of congestion of the mucous membrane, and acute or chronic gastritis; and as these affections constantly co-exist with other diseases, great variety as regards the desire for food is manifested in various complaints. In acute gastritis there is often not merely a loss of desire for, but a positive aversion to food, and the patient resolutely resists any attempt at obliging him to take either solid or liquid nourishment. In the more chronic forms of gastritis the distaste for food may be only slight; in some cases the appetite is increased, but is quickly satisfied as soon as a small quantity of food is taken. In chronic ulcer of the stomach the appetite, as a rule, remains good, and the patient is only prevented from indulging it by the fear of the pain that will result from so doing. Whenever the secreting structure of the organ is extensively diseased the appetite fails. Thus, in atrophy of the stomach the desire for food generally lessens along with the diminishing strength of the invalid. In cancer of the stomach there is always an extensive destruction of the glandular structure, and loss of appetite is a constant and prominent symptom. It must be remembered that a loss of appetite may be more apparent than real. The physician is constantly consulted on account of this symptom, when a little inquiry will show that the patient is really digesting as much as his system requires, but that by a habit of eating without allowing a proper interval between his meals, or by indulging in food of too nutritious a nature, or in an undue amount of alcoholic stimulants, hunger is prevented. For *Anorexia nervosa* see NEURASTHENIA.

Increase of appetite—*Bulimia* usually occurs where there is a necessity for an increased supply of food. Thus it is common after all febrile diseases, where the stomach has been long inactive. Again, in diabetes, where a large portion of the food is passed off in the form of sugar instead of being converted into the material required to keep

up the nutrition of the body, there is an unusually large appetite. A craving sensation is a common symptom in chronic catarrhal gastritis. It probably arises from the irritation set up by the mucus and fermenting substances long retained in the stomach, and is temporarily relieved by eating. The best treatment for such cases is to give alkalis about half an hour before the craving usually occurs, at the same time that the affection of the mucous membrane is combated by appropriate diet and remedies. In some persons the sensation of extreme hunger appears to arise from an irritable condition of the stomach, by which the food is passed into the duodenum before digestion is completed. The sensation is mostly complained of at night, and the writer has found it a good plan to let the patient have some beef-tea or meat-lozenges, for example, either just before retiring to rest or during the night. In children a craving for food is a frequent symptom, and arises either from the irritation of worms, or from chronic catarrh of the mucous membrane of the small intestines.

Perversion of appetite (Pica).—Is most common in pregnant or hysterical females. Articles, such as chalk, cinders, and slate-pencil, are sometimes swallowed. In the insane and in idiots articles of an indigestible nature, such as string, paper, cocoanut fibre, are not infrequently introduced into the stomach.

It is a matter of great importance that all persons, but especially dyspeptics, should accustom themselves to control their appetites. Whenever a larger amount of food is taken than the stomach is capable of digesting, the residue is apt to ferment and thereby to produce gastric catarrh. This is more especially the case where the digestive powers have been enfeebled by previous attacks of gastric inflammation. S. FENWICK.

APYREXIA (ἀ, priv.; and *πυρεσσω*, I am feverish).—Absence of fever. It is often used to denote the interval between two paroxysms of intermittent fever. See FEVER.

ARACHNITIS.—Inflammation of the arachnoid membrane. See MENINGES.

ARCAÇON, West Coast of France. Summer and winter resort. Part near sea frequented in summer. Winter resort on higher ground among pine-woods. Equable temperature. See CLIMATE, Treatment of Disease by.

ARCUS SENILIS.—SYNON.: Gerontoxon.

DESCRIPTION.—Arcus senilis is a crescentic or annular opacity just within the margin of the cornea, often seen in old persons. It usually begins as a greyish or whitish crescent at the upper part of the cornea, and subsequently a similar crescent makes its appearance in the lower part. These crescents gradually increase in opacity, in width, and in length, until their horns coalesce and form an *annulus* or ring. A true arcus is not quite continuous with the sclerotic, but is separated from it by a narrow rim of transparent cornea. The breadth of the crescent or ring generally ranges from one-twentieth to one-tenth of an inch. The opacity is more pronounced at its outer border, but fades insensibly towards the central portion of the cornea, which is of normal transparency.

ÆTIOLOGY AND PATHOLOGY.—The proximate causes of arcus are not known. Some families are

especially prone to it, and it most frequently occurs in persons of fifty years of age and upwards. The opacity is commonly believed to be due to fatty degeneration of the corpuscles and fibrillæ of the cornea, and to be indicative of degenerative changes within the heart and blood-vessels and other textures. There is, however, a growing consensus of opinion that its pathological as well as clinical significance has been overrated. Certainly it is, in itself, no criterion of age, either as regards years or constitution. On the one hand it may occur in young persons, and on the other hand it may be absent in extreme old age. Again, it may exist in persons free from any appreciable signs of arterial or cardiac disease, and it may be absent from those who have pronounced degeneration of the heart and blood-vessels. It is, nevertheless, true that arcus senilis is due to degenerative changes within the cornea, and that it does sometimes co-exist with atheroma or with fatty heart. According to some investigations made by the writer, in conjunction with Mr. E. T. Collins, in the laboratory of Moorfields Eye Hospital, the change in the cornea consists of the presence of fine highly refractive molecules, distributed along the course of the lymphatic spaces and channels of the superficial layers of the periphery of the cornea near the loop-endings of the capillaries of the conjunctival and episcleral blood-vessels. The greater portion of these molecules are not fatty, as is generally supposed; for, unlike fat, they are neither blackened by osmic acid nor dissolved by ether. They probably arise from mucoid degeneration of the protoplasm within the lymphatic channels and spaces of the cornea, and to some extent of the fibrillæ themselves. A few doubtful, blackened, fatty molecules may be seen here and there in sections stained by osmic acid. The fibrillæ are slightly wrinkled, and are more loosely held together than natural, and the spaces between the laminae are wider. In support of the non-fatty nature of arcus senilis it may be stated that wounds of the cornea, whether through the opacity, or to its inner side, or to its outer, and whether surgical or traumatic, heal in a natural way.

TREATMENT.—The condition is incurable, and is unaffected by any kind of treatment.

JOHN TWEEDY.

ARDOR (*ardor*, heat).—A sensation of heat, burning, or scalding. It may be felt either along the urethra during the passage of urine (*ardor urinae*), or in connection with the stomach (*ardor ventriculi*).

ARGYRIA (ἀργυρος, silver).—The slate-coloured stain of the skin produced by the internal use of the salts of silver. See PIGMENTARY DISEASES OF THE SKIN.

ARKANSAS SPRINGS, in Arkansas, United States.—Thermal waters. See MINERAL WATERS.

ARSENIC-HABIT.—See DRUG-HABITS.

ARSENIC, Poisoning by.—Arsenic is classed as a metallic irritant poison, though its action is by no means limited to that of an irritant. It acts specifically on the gastro-intestinal mucous membrane, whatever be the channel by which the poison gains access to the system. The most usual source of acute arsenical poisoning is the administration of

white arsenic or arsenious acid; but the sulphides, various arsenites, and impure commercial articles, such as dyes, wall-papers, articles of food, beer, and pigments, may be fertile sources of arsenical poisoning. Poisoning by arsenic may be either *acute* or *chronic*.

ANATOMICAL CHARACTERS.—These are the same by whatever channel the poison has gained access to the system. There is marked petechial inflammation of the stomach and duodenum, usually of the small and large intestines also; but not uncommonly the inflammation is limited to the stomach, duodenum, and rectum, the intervening alimentary tract having escaped. If the poison has been administered in a solid form, white patches of the arsenical compound may be found embedded in yellow or bloody mucus and inflammatory exudation. Portions of the white arsenic are also sometimes converted by the sulphuretted hydrogen evolved during decomposition into the yellow sulphide. Ulceration of the stomach is rare. Neuritis may be observed. An echymosed condition of the heart is often noticed; and fatty degeneration of the liver, as in poisoning by phosphorus, has been described.

A. Acute Arsenical Poisoning.—This is the usual form of poisoning ensuing on the nefarious administration of any preparation of arsenic, but usually the oxide (*arsenious acid*) is employed.

SYMPTOMS.—The symptoms do not, as in the case of corrosive poisoning, come on immediately after the administration of the poison. There is most commonly an interval of half an hour or an hour between the swallowing of the agent and the onset of prominent symptoms. The quantity of the noxious agent, and its state as regards solubility, have also an obvious relation to the commencement of symptoms. Most commonly, after a sense of faintness and depression, intense burning pain is felt in the epigastric region, accompanied by tenderness on pressure. Nausea and vomiting quickly supervene, increased by every act of swallowing. Unlike what occurs in an ordinary bilious attack, with which arsenical poisoning may be at first confounded, the pain and sickness are not relieved by the act of vomiting. The vomited matters are extremely varied, and present no characteristic appearances. At first they usually consist of the ordinary contents of the stomach, but at a later stage are largely charged with bile which has regurgitated into the stomach in consequence of the violence of prolonged emesis; and they may be tinged with blood. In most cases vomiting is speedily followed by violent purging, and great straining at stool, the motions being often streaked with blood. Purging may, however, be entirely absent. Other prominent symptoms are great thirst, a feeble irregular pulse, and cold clammy skin. The patient, as a rule, dies within eighteen to seventy-two hours, in a state of collapse; but tetanic convulsions are not uncommon, and even coma and paralysis may close the scene.

DIAGNOSIS.—From an ordinary bilious attack, induced by improper diet or by decomposing food, arsenical poisoning is diagnosed by the persistence of the symptoms after the removal of the apparent cause; and not infrequently by the symptoms remitting and again supervening on the administration of food or drink of a particular kind, or given by a particular person. From choleraic diarrhoea it is distinguished by the *sudden* onset of symptoms, thirty to sixty minutes after food or drink has been

taken; by the absence of rice-water stools, or of lividity of the skin; and by the symptoms not yielding to treatment. Moreover, in poisoning by arsenic, there is usually greater tenderness over the epigastrium; the diarrhoea is less passive, and accompanied with more tenesmus than in choleraic diarrhoea; the stools are more often bloody; and nervous symptoms may be more pronounced. The diagnosis is, however, often very difficult, except when aided by a chemical analysis of the matters ejected from the stomach or of the excreta, which should always be made in doubtful cases.

PROGNOSIS.—This must always be uncertain, since it is rarely possible to ascertain the quantity of poison taken, or to ensure its entire evacuation from the stomach.

TREATMENT.—Emetics, diluents, and demulcents are the appropriate remedies. The stomach-pump may also be usefully employed. In administering emetics, tartar emetic should be avoided, as it increases the depression, and its presence complicates a chemical analysis. Moreover, tartar emetic sometimes contains traces of arsenic, and, in the event of an analysis being made, an unfounded suspicion may be raised. No confidence can be placed in the so-called antidote, *ferric hydrate*, but dialysed iron may be freely given.

B. Chronic Arsenical Poisoning.—This form of poisoning is not uncommon, and is, unlike the acute form, generally accidental. The inhalation of arsenical vapours in factories, or of arsenical dust, as from green and other wall-papers, and in the process of manufacturing artificial flowers, is a common source of chronic arsenical poisoning.

Those who are chiefly exposed to this form of poisoning are persons employed in the manufacture of pigments, especially green pigments; paper-hangers and decorators; manufacturers of artificial flowers; milliners; persons exposed to the fumes of heated metals, particularly zinc and brass; manufacturers of dyes; and leather-dressers (*see OCCUPATION-DISEASES*). In the process of depilating sheep-skins, previous to the tanning or the tawing process, a mixture of lime and orpiment (*sulphide of arsenic*) is used; and serious ulceration of the hands, scrotum, nose, and cheeks not infrequently results. Persons living in rooms the walls of which are covered with arsenical paper, especially bright green papers containing arsenite of copper, are liable to suffer from chronic arsenical poisoning. It is uncertain whether this is entirely caused by the mechanical transfer of pigmentary dust to the air-passages, or is partly due to volatilisation of the arsenic, probably in the form of arseniuretted hydrogen. Many brown wall-papers also contain arsenic, and arsenious acid is sometimes added to the size; such papers have been known to produce the specific symptoms of arsenical poisoning.

That some persons can take arsenious acid internally with impunity in relatively large doses (arsenic-eating) is now a well-established fact.

SYMPTOMS.—The first symptoms of chronic arsenical poisoning are usually loss of appetite, precordial pains, irritability of the bowels, and occasionally headache. Suffusion of the eyes, a peculiar and characteristic appearance of the conjunctiva, often amounting to actual conjunctivitis, puffiness beneath the eyelids, and intolerance of light are early manifested. The muscular power of the limbs is impaired pretty constantly, and actual paralysis, extending upwards from the lower extremities, is

occasionally observed (*see* PARALYSIS, TOXIC). A brownish or sepia pigmentation of the skin of the face, neck, axillæ and abdomen, and thickening of the horny layers in the palmar and plantar regions, may be noticed. Males who handle arsenical preparations are liable to ulceration of the scrotum and penis, obviously due to a mechanical transference of the poison to the genitals when these are touched. Herpes and other affections of the skin are observed. Multiple neuritis is common. If the source of the disease be not removed, progressive emaciation, exfoliation of the cuticle, and nervous prostration supervene; and convulsions may precede the fatal termination. The effects of green arsenical pigments are sometimes manifested by bleeding from the nose.

DIAGNOSIS.—When a patient suffers more or less from the symptoms above described, and is also known to be exposed to any of the sources of danger from arsenical poisoning enumerated above, the diagnosis is not difficult.

TREATMENT.—The source of poisoning should invariably be removed. It is found that those who suffer from working in arsenic make no progress towards recovery until they are removed from contact with the poison. Wall-papers which contain arsenic, and are suspected to be the cause of symptoms, should be taken away. Quinine, or other tonics, iron, and attention to the digestive organs will be needed. Removal to fresh country air is often productive of marked benefit. Soothing lotions to the skin, and careful attention to eroding ulcers, especially of the cheek, may be necessary. Shampooing and warm baths form the best treatment for paralytic lesions.

T. STEVENSON.

ARTERIES. Diseases of.—I. **Arterio-Sclerosis.**—This disease will be described as consisting of two varieties, (1) *General or diffuse arterio-sclerosis*, and (2) *Local or nodose arterio-sclerosis*.

1. **General or Diffuse Arterio-sclerosis.** In this condition there is an increased rigidity of the arteries, due to a thickening of their walls involving mainly the inner coat. The process may be either generalised or limited to certain arteries, may affect the large vessels only, or leave them intact and select the smaller arteries. In its more advanced stage it is often termed *atheroma*, or *endarteritis deformans*.

ÆTIOLOGY.—Arterio-sclerosis is a physiological process in old age, but it may also occur in young adults, without any obvious direct cause, when there is an inherited tendency to disease of the arteries. Of the direct causes the most important is probably long-continued muscular strain, especially when associated with unfavourable conditions, such as exposure or insufficient food. Gout and articular rheumatism are very common forerunners of the disease, as are also certain infective and toxic processes, especially syphilis (congenital or acquired), scarlet fever, influenza, endocarditis, typhoid fever, and malaria. It may be produced by the action of alcohol, lead, or phosphorus, and in many cases is the result of auto-intoxication from habitual over-eating. It also occurs as a constant feature in chronic interstitial nephritis. As regards *sex*, men are as a rule more affected by arterio-sclerosis than women owing to their greater exposure to its causes; but since women become more subject to the disease after the climacteric, the liability of the two sexes tends to become equalised after fifty.

PATHOLOGY.—Sclerosis of the smaller arteries is

most generally diffuse in its distribution, but tends to involve specially the arteries of the brain, kidney, and heart, and of the distal parts of the upper and lower extremities. The distribution of the lesion is seldom uniform, but affects the various areas in different degree according to peculiarities of individual constitution or of the ætiological factors.

The sclerosis of the artery affects mainly the inner coat, which becomes thickened by the formation of dense layers of fibrous tissue owing to the proliferation of the sub-endothelial connective-tissue cells. This thickening is never uniform, and is generally greater at one side of the vessel—that which is exposed to the greatest strain. The elastic lamina becomes granular and its continuity may be interrupted. The condition of the media varies considerably. Where there has been high arterial tension, as in chronic interstitial nephritis, the muscular fibres may be hypertrophied; indeed, this may be the main source of the thickening of the artery. In other cases it may be the seat of hyaline, fatty, or even calcareous degeneration, and may show patches of nuclear proliferation, especially around capillaries which have entered the coat. The tunica adventitia may be normal or show some thickening, usually slight in degree. The affected vessels increase in length as well as in thickness, so that they become tortuous, as can be well seen in the temporal and radial arteries. When palpated the artery feels resistant and cord-like, rolling under the finger in a characteristic manner. The amplitude of the pulse-wave is diminished.

The mode of production of this process is still *sub judice*. In the opinion of Thoma, which is entitled to great weight, the first step in the process is a diminution in the contractility of the muscular wall of the arteries, as a result of long-continued overstrain or of the direct action on it of some of the toxic substances already mentioned. The affected arteries become dilated, and to compensate for this the inner coat becomes thickened. In consequence of the new-formation of fibrous tissue, the artery becomes more rigid and thus offers greater resistance to the blood-stream. Two sets of effects arise directly from this. The heart hypertrophies to overcome the increased resistance, and this hypertrophy causes an increased strain on the arterial walls leading to their further sclerosis, which in its turn is productive of further hypertrophy of the heart. So long as the strain is not excessive and nutrition is well maintained, the hypertrophy and sclerosis may balance each other, but a time generally arrives when degenerative changes appear in the arteries, in the heart, or in both together. In the arteries, the changes appear as a partial hyaline degeneration, with the subsequent formation of fatty and calcareous deposits (*atheroma*), so that eventually yellowish patches are visible on the vessel walls. The calibre of the artery loses its uniformity, and may vary very greatly, while the rigidity of the artery causes it to gape when transversely divided. Subsequently the endothelium may become eroded, and the contents of the atheromatous patch may be discharged into the circulation, leaving a rough surface on which thrombi may be deposited, thus leading possibly to the occlusion of the vessel (for other changes which may occur *see* ANEURYSM, and BRAIN, HÆMORRHAGE INTO). The degenerative changes which appear in the heart may be due to exhaustion from the continued over-strain produced by the increased peripheral resistance, from

participation in the general toxic process, or from sclerosis of the coronary arteries. The compensatory hypertrophy fails, dilatation increases, and mitral incompetence ensues, with the usual signs of failure of compensation. Anginous and syncopal attacks may occur, especially when the coronary arteries are affected, and there is increasing breathlessness on exertion. Pathologically the muscle of the heart may show brown atrophy or fibroid or fatty changes, and when the branches of the coronary arteries become narrowed or impervious, localised areas of softening appear. Rupture of the heart may occur spontaneously or after sudden strain. These morbid conditions of the heart and vessels lead to evident general changes. There is anemia and lowering of the nutrition generally, shown either by emaciation and atrophy (as in the senile form), or by flabbiness in more obese patients. Digestion is impaired, and the appetite becomes capricious. The loss of vaso-motor control is the cause of attacks of vertigo, or even syncope, especially on changing position suddenly, and epileptiform seizures may occur.

As the disease progresses mental phenomena may appear, such as irritability, a feeling of torpor, and incapacity for clear, connected thought; and at intervals there may be temporary attacks of absence of mind without loss of consciousness, in which external circumstances pass unnoticed. This has been named lately the 'temporary aberration' of elderly people. Its practical significance as regards certain occupations demanding continuous attention is very obvious. As a rule there is marked insomnia. Headache, migrainous in some cases, is common, and tingling or numbness may be felt in the extremities. Cramp is often troublesome, especially at night, occurring either spontaneously, or after some unusual muscular fatigue. When the arteries are gravely affected and the heart weak, these sensory symptoms may be the precursors of gangrene, due to the occlusion of the vessels by thrombi and the failure of the collateral circulation. This occurs most readily in the senile form of arterio-sclerosis. Hemorrhages may also occur readily from rupture of the arterial walls, more especially of the cerebral vessels. Pain, most marked in the extremities, is often present, and is generally regarded as rheumatic in origin. Thoma terms it 'angio-neurotic' pain and points out that it is probably due to affection of the nerve-endings in the arterial walls.

The pathological permeability of the capillaries leads to localised serous accumulations from hypostasis. The oedema varies according to position, being present in the feet at night and in the eyelids in the morning. Serous effusions into the closed cavities also occur readily, more especially in the pleural sac, and there is also a marked tendency to cerebral oedema. Polyuria is usually present, similar to that which occurs in chronic interstitial nephritis, and sometimes due to pathological changes in the kidney, in addition to the general vascular changes. Frequency of micturition at night is one of the characteristic features of sclerosis of the renal arteries. The urine has a low specific gravity and there may be albuminuria, often transient. Pulmonary changes are shown by the ready occurrence of bronchitis and asthma.

The general impairment of nutrition and the changes in the vessels lessen the normal reaction to inflammatory lesions, and for this reason in cases of

arterio-sclerosis the danger of acute inflammations, such as pneumonia, and of surgical operations is greatly increased.

The physical signs in the circulatory system are characteristic. The left heart may be hypertrophied or dilated, its apex being displaced downwards and outwards. The sounds over the mitral area are normal; or, in later stages, there may be a systolic murmur. In the aortic area the second sound is accentuated. The radial artery is thickened and may be incompressible. The pulse-wave is smaller than in health. The sphygmographic tracing shows a slow rise, a rounded top, and a delayed and small dirotic wave.

TREATMENT.—When fully established the disease is incurable and tends to be progressive, but much may be done to arrest or delay its course and to ameliorate the symptoms, especially if treatment is begun early, and if the cause is removable, as is the case with alcoholism and plumbism. Preventive treatment should be adopted in members of families in which there is a tendency to arterial disease, or to gout or rheumatism. Such individuals should be warned as to their special liability to vascular weakness, and their lives should be regulated as far as possible in accordance with the principles of the general treatment advised below.

The general treatment is of the first importance in dealing with arterio-sclerosis, and consists chiefly in a very careful regulation of the daily life in relation to exercise, occupation, and diet. The exercise should be moderate in amount, in due proportion to the powers of the individual, always stopping short of fatigue, and should be taken regularly, since moderate exercise tends to lower the vascular tension. Emphasis should be laid on the necessity for avoiding any sudden violent muscular exertion, or any prolonged strain even when moderate. Especially must the subjects of arterial disease be warned not to run to catch a train or omnibus, or to make any rapid ascent. Sudden mental or emotional shock, or long-continued worry should be also guarded against. When feasible a quiet existence involving a fair amount of light outdoor employment should be advised. The dietary should be simple and should consist of three light meals a day with an interval of four or five hours between them. Sweet wines and malt-liquors must be forbidden, but where some stimulant is necessary, well-diluted whisky may be taken with the solid food. As a general rule it is advisable to take the requisite amount of fluid between rather than during meals. The skin should be kept acting freely by the use of warm clothing and of frequent baths. A daily evacuation of the bowels is necessary. The place of residence should be in an equable and moderately warm climate and at a low altitude. The subjects of arterial disease should never ascend to any great height.

When the vascular changes are fully established two main indications as regards treatment arise:—viz. the moderation of the peripheral tension and the nutrition of the hypertrophied heart. To obtain the first the iodides and the nitrites may be used, and such cardiac tonics as arsenic and strychnine in small doses may be employed to act directly on the cardiac muscle, and also on the general nutrition. Any tendency to dyspepsia must be controlled by the usual means, and occasional free purgation obtained by the use of a mercurial followed by a saline draught. In late stages of the disease, when

the heart-muscle weakens and compensation fails, cardiac tonics such as digitalis and strophanthus must be resorted to, but these should always be used in combination with the iodides or the nitrites in order that the peripheral tension may be lessened at the same time.

These different details of treatment are often carried out most easily during residence at a watering place, the choice of which must depend upon the special features of each case.

The various complications, such as angina pectoris, asthma, gangrene, insomnia, must be treated as they occur.

2. Localised or Nodose Arterio-sclerosis may be found in the larger or the smaller arteries. It may exist alone or may be combined with the diffuse form. It is specially met with in the arteries which are subjected to the highest blood-pressure, such as the aorta, the arteries of the lower extremities, of the brain and, in obstructive mitral disease, of the lung. In the aorta, in the early stages of the disease, the patches appear as irregular, slightly raised areas, of the consistence and colour of hyaline cartilage. Later, when degeneration takes place within them, the patches become yellow and opaque in the centre. In what may be termed their final stages, they show calcareous plates of various sizes. There is always a certain amount of irregular dilatation of the affected vessel, especially in the case of the aorta, hence the name often given to it of *arteritis deformans*. The process seems, according to the researches of Thoma and his pupils, to be secondary to localised weakening of the middle coat of the artery. This weakening leads to a local yielding of the coat, which bulges outwards. The proliferation of the intima and of cells which penetrate into it along with the vasa vasorum which grow in the adventitia, produces the dense laminated fibrous tissue found in the first stage. This must be looked upon as a process compensating for the weakening of the media. In course of time the continued stretching of this new tissue affects its nutrition, so that there follows hyaline, then fatty, and finally calcareous degeneration, especially in the deeper parts of the thickened intima. The change, however rare, remains limited to the intima. The weakened media may also show a proliferation round the vessels which penetrate into it from the outer coat, and it may in its turn become the seat of fatty and calcareous degeneration.

The consequence of sclerosis of the larger vessels, such as the aorta, will be referred to under the sections on AORTA, Dilatation of the, and ANEURYSM.

II. Syphilitic Arteritis. 1.—**SYPHILITIC ENDARTERITIS.**—This is in most cases a chronic affection of the intima, differing from arterio-sclerosis in two important respects. It does not undergo fatty or calcareous degeneration, although it may occasionally show a tendency to caseation; and it tends to narrow or to obliterate the lumen—hence the name *obliterative endarteritis* often given to it. Such obliteration does not occur in ordinary sclerosis unless a thrombus forms within the vessel and undergoes organisation. Syphilitic endarteritis affects mainly the arteries of the brain, the spinal cord, and the heart, but it does not altogether spare the arteries of the extremities. It is as yet undetermined whether it may occur in the aorta, although the relation of aneurysm to sclerosis of the aorta and to syphilis suggests this possibility very strongly.

In the brain the anterior and middle cerebral arteries in their cortical and internal branches appear to be most frequently affected; but no artery within the cranium is altogether immune. The affected portions of the arteries appear greyish-white, and finally resemble firm greyish threads or solid cords (*see* BRAIN, Syphilis of; Tumours of). Microscopically, there is an irregular, often nodular thickening of the intima, which at first is loose in texture and composed of spindle or stellate cells, and later becomes more condensed and fibrous. The elastic lamina is often granular and may appear double. The middle coat may appear normal or may be more or less infiltrated with round cells. The outer coat also may show similar infiltration. The vasa vasorum may penetrate through the media into the thickened inner coat and even into any thrombi forming in the lumen. The symptoms of syphilitic endarteritis are mostly those of ischaemia of the organ affected. If the coronary arteries are involved there may be the sign of heart-weakness and even rupture. Endarteritis of the cerebral arteries may cause transient or permanent disorders of speech, paresis or paralysis, confusion of thought, impairment of memory, and insomnia. If the spinal arteries are attacked the symptoms of myelitis will be produced. If the arteries of the extremities are involved they may be felt as solid cords; the distal parts may be cold and livid; and there may be even limited gangrene of parts of the fingers or toes. In estimating the possibility of recovery of function when the brain or spinal cord is involved, one must remember that a portion of the nerve-tissue may have undergone permanent softening before treatment is begun, but that, on the other hand, the symptoms may be due merely to a temporary disturbance of the circulation. The tendency to relapse in all cases must also be borne in mind. Antisyphilitic treatment must be vigorously pushed and continued till long after the symptoms have disappeared or become stationary.

2. **SYPHILITIC PERIARTERITIS** may occur independently of any endarteritis or may be associated with it. The process affects mainly the arteries of the brain, viz. those in the cerebellar cortex, those of the medulla and pons, as well as the arteries of the interior of the cerebral hemispheres and of the nuclei of the cranial nerves. It occurs in three forms, a diffuse, a nodular, and a gummatous caseating form. Of these the first-named tends to appear the soonest after the original infection, sometimes as early as six or nine months. It leads to a diffuse infiltration of the adventitia and of the perivascular lymph-space with round cells, a similar but slighter infiltration of the middle and inner coats, and a tendency to early thrombosis with consequent softening of the part supplied. The nodular form produces minute excrescences on the wall of the artery, about the size of a pin's head and resembling in miniature the gnarling seen on old oak trees. These are also composed of round and plasma-cells, with a slight tendency to caseation. This form may be combined with the diffuse variety. In the caseating form, which represents the most chronic variety, the nodules are larger, reaching the size of split peas and showing distinct caseation. They appear later in the history of the disease than either of the previous varieties. Periarthritis may be suspected if cerebral symptoms appear within a short period of syphilitic infection, and calls for very vigorous and persistent anti-syphilitic treatment.

III. Nodose Periarteritis.—There is a form of nodose periarteritis, due to some as yet undiscovered probably infective cause, which runs a rapid course and is accompanied by wasting and enlargement of the spleen. This form presents both macroscopic and microscopic appearances very similar to those found in syphilitic periarteritis. It tends to produce thrombosis, but it differs from the syphilitic form in the frequent occurrence of aneurysmal dilatations of the weakened vessel-walls. The affection seems to spare the cerebral arteries and to involve those of the muscles and of the various thoracic and abdominal viscera, which are studded with small whitish nodules.

IV. Acute Arteritis.—This may arise from infection of an artery by pyogenic organisms which gain access to its walls either from the blood-stream or from the surrounding tissues. The aorta immediately above the semilunar valves is not infrequently, during the course of an ulcerative endocarditis, injured by the impact of a portion of vegetation on one of its cusps, which may be driven against the intima by the force of the blood-current. Micro-organisms derived from the vegetation attack the intima and give rise to a verrucose endarteritis similar to that already present on the valves. Then may follow necrosis and softening of the wall with the formation of an acute aneurysm which may rupture into the pericardial sac or between the coats of the artery. Again, if a portion of vegetation containing septic organisms be transported to and impacted in a distant artery, it will cause suppurative necrosis of the wall of the artery with the formation either of an abscess or of an embolic aneurysm which readily ruptures. The arterial coats may also be attacked from without by an inflammatory process in the tissues. In such cases a thrombus is always formed; this will be simple or puriform according to the nature of the causal condition. It is well to note that a bright or brownish-red staining of the intima so frequently seen *post mortem* is not an indication of arteritis, but is due to staining by hæmatin liberated from the blood-corpuscles after death. The symptoms of an arteritis are always obscured by those of the general condition which produce it. It is doubtful if the symptoms assigned to acute arteritis, viz. acute dilatation of the aorta, a systolic aortic murmur, dyspnoea, and cough, are really due to the process in question.

V. Fatty degeneration of the arteries may be present apart from atheroma, and may occur as a senile process, in anemia or in marasmus, or may be found in certain individuals without any obvious cause. The process appears in the intima, forming opaque, velvety, yellowish areas, which tend to become eroded, so that a portion of the intima is destroyed. The muscular coat, which is usually fatty also, may yield to the localised strain and rupture, the result being either the formation of a dissecting aneurysm, or, if the outer coat yields, rupture of the artery. These grave conditions are, however, seldom met with as a result of uncomplicated fatty degeneration.

VI. Calcareous degeneration of the arteries, unassociated with atheroma, is rare. It is almost exclusively a senile change, but has been known to occur in young subjects. It usually attacks the middle coat of the arteries, and affects mainly those of medium size, especially in the brain and the extremities. The arteries may become converted into rigid tubes from the deposit of calcareous salts

between the muscular fibres. The effect of the rigidity of the vessels on the nutrition of the heart and of the tissues is practically identical with that produced by advanced arterio-sclerosis.

VII. Amyloid degeneration of arteries.—*See* AMYLOID DEGENERATION.

VIII. Hyaline degeneration of arteries.—*See* DEGENERATION.

ALEXANDER BRUCE.

ARTERIES, Examination of.—*See* PHYSICAL EXAMINATION; and PULSE.

ARTHRALGIA (ἄρθρον, a joint; and ἄλγος, pain). Pain in a joint. The term is more particularly applied to articular pain in the absence of objective disease. *See* JOINTS, Diseases of.

ARTHRITIS (ἄρθρον, a joint).—A term generally used to signify any disease whatever involving a joint, but more correctly confined to articular inflammation. It is also employed to designate inflammation of *all* the structures forming a joint, as distinguished from mere synovitis. *See* JOINTS, Diseases of.

ARTHRODYNIA (ἄρθρον, a joint; and ὀδύνη, pain).—Pain in a joint. *See* ARTHRALGIA.

ARTICULAR RHEUMATISM.—Rheumatism affecting joints. *See* RHEUMATISM, ACUTE.

ARTIFICIAL RESPIRATION.—The method of exciting and keeping up the movements of the chest, so as to supply air to the lungs, is a subject of the highest importance, since the hopes of recovery depend on its due performance in many cases of narcotic poisoning, in the apparently drowned or asphyxiated, and in the collapse of the advanced stage of the condition induced by anesthetics.

PRECAUTIONS.—For its effective employment it is essential to see that no foreign body obstructs the air-passages. Children and old people are liable to swallow large pieces of meat or crust, which become impacted in the pharynx or œsophagus. In operations upon the nasopharynx portions of new-growth or clots of blood may occlude the rima glottidis; even in Dental Surgery under Nitrous Oxide the possibility of broken instruments, broken props, and teeth, more especially wisdom-teeth and bicusps, becoming impacted in the larynx should never be overlooked.

Artificial dentures may become dislodged and wedged in the pharynx, and vomited material may gain entrance to the larynx. In all cases therefore of suspended respiration the mouth should be opened and the finger swept round the oral cavity and pharynx, and any foreign body dislodged before commencing artificial respiration; should, however, a foreign body be detected which cannot be at once removed, then immediate laryngotomy followed by artificial respiration is the only treatment likely to be followed by success. Tracheotomy is rarely necessary in an uncomplicated case. A knife-handle held between the molar teeth is a ready and useful gag to keep the mouth open. A button-hook, in the absence of pharyngeal forceps, is sometimes very serviceable. Vomited matter should be quickly removed with a sponge or cloth twisted round a

piece of wood or more readily with the hooked index finger. For the special treatment of persons drowned see DROWNING, Death by.

METHODS.—The simplest method of commencing artificial respiration is to compress the chest and abdomen simultaneously, then remove pressure so as to allow air to enter the chest, and again repeat the pressure every two or three seconds. If the sound indicates that air is passing into and out of the lungs, this method may be continued until spontaneous breathing returns; but if we are not sure that the air is exchanged, and in all cases if the patient's condition is not decidedly improved in half a minute, we should resort to one or other of the following methods:—

1. *Howard's method.*—This method is so important that it is considered separately under RESUSCITATION.

2. *Sylvester's method.*—Place the patient on his back on the floor, with a block or pillow under his shoulders in order that the head may become partially extended; then kneel at the patient's head and grasp the arms above the elbows; press them first well into the sides in order to expel air, then drag them outwards and upwards over the head until they are in a line with the trunk, and keep them in this position so long as air enters the chest. Some arrangement is needed to prevent the body from being dragged towards the operator. For this purpose the plan of raising the chest on a high cushion or box has been adopted, but as a condition of cardiac anemia is often present, this is objectionable. It is better to effect the object by placing a book in front of the thighs while kneeling at the head of the patient. It may be needful to draw forward the tongue; but generally if the head falls back over a cushion placed behind the neck, this is not required. An artery-forceps, or a noose of string, or a handkerchief will enable an assistant to keep the tongue well forward.

As soon as the sound produced by the entrance of air into the chest ceases, the arms should be brought down to the side and a little towards the front of the chest, and pressed firmly and steadily against it for about one second after air is heard escaping. In cases of drowning it is enough to repeat this operation every four seconds, but in the collapse resulting from chloroform or other anæsthetic, the necessity for getting the vapour quickly out of the chest justifies a more rapid performance of the movements during the first five minutes. After this time the movements should be carried on more slowly, but they should be continued for half an hour at least, and even longer if the warmth of the surface and diminution of lividity give any reason to hope that the heart has not entirely ceased to act.

3. *Marshall Hall's ready method.*—This is performed by placing the body on its face, the thorax being supported upon a roll of clothing, cushion, or pillow; firm pressure is made on the back to produce expiration, and then the body is rolled on to its side to produce inspiration; this alternate rolling from the face to the side should be repeated about fifteen times a minute. It is recommended in cases of drowning, as fluids can drain away from the mouth and so clear the upper lung. The plan is not nearly so effective as Sylvester's, but if no assistant is at hand it is the best mode of artificial breathing that can be adopted.

4. *Mouth-to-mouth insufflation.*—This method is not to be depended upon, because of the difficulty

both of keeping the larynx open, and also of preventing the air going down the gullet.

The administration of *oxygen* is indicated in most cases of artificial respiration where the cyanosis is deep, but unfortunately it is not readily attainable. Now that the gas can be had in a compressed state, and can be given by means of a tube or an inhaler, it will probably be more extensively utilised; but it is certain that in all cases of impending asphyxia, time is of so much importance that anything which would delay the supply of oxygen would not be compensated for by giving it pure, instead of in the form of common air. Tracheotomy is not to be thought of in the first instance in any case in which air can be made to pass, even in very small quantity, through the trachea.

For supplemental and after-treatment, see RESUSCITATION.

ASCITES (ἄσκός, a leathern sac: a large belly).
SYNON.: Dropsy of the peritoneum; *Hydrops peritonei vel abdominis*; *Hydroperitoneum*. Fr. *Ascite*; Ger. *Die Bauchwassersucht*.

DEFINITION.—An accumulation of fluid within the cavity of the peritoneum more or less serous in character.

ÆTIOLOGY AND PATHOLOGY.—Ascites occurs in the course of many different diseases. It may be due to any of the following causes:—

I. Direct mechanical obstruction affecting the portal circulation.

1. Obstruction of the trunk of the portal vein before it enters the liver, either from external pressure or an internal block.

2. Pressure upon or obliteration of the branches of the vein within the liver.

3. Pressure upon the hepatic veins, or upon the inferior vena cava after it receives these veins.

II. Cardiac or pulmonary diseases obstructing the general venous circulation.

III. Disease of the kidneys.

IV. Morbid conditions of the peritoneum.

V. Miscellaneous.

I. Any direct obstruction interfering with the portal circulation must necessarily lead to congestion and over-distension of its tributaries, one of the consequences of which is excessive transudation of fluid into the peritoneal cavity, while absorption is checked. See DROPSY.

1. The portal trunk may be pressed upon, as it lies in the fissure, by prominences from the liver itself, enlarged glands in its vicinity, a neighbouring tumour (as cancer of the pancreas, or a growth in the small omentum), a hepatic aneurysm, or inflammatory thickening resulting from peri-hepatitis. The pressure may absolutely close up the vessel, but it more commonly causes a local clot to form, and thus its channel is blocked. A thrombus is also, in exceptional instances, produced in connection with a diseased condition of the portal vein, such as inflammation or calcification; obstruction to the circulation within the liver; or feebleness of the circulation, with an abnormal tendency to coagulation of the blood.

2. Pressure upon, or obliteration of, the branches

of the portal vein within the liver can only arise as a consequence of some morbid condition involving the actual substance of this organ. The hepatic disease which most commonly leads to this result, and which is one of the most frequent causes of ascites, is cirrhosis of the liver. Occasionally it accompanies syphilitic and other forms of contracted and indurated liver, or it may be associated with infiltrating cancer. Occasionally a mass within the liver obstructs a considerable branch of the portal vein.

3. Obstruction of the hepatic veins, or the upper end of the inferior vena cava, is a rare event, but may arise from the pressure of a growth connected with the liver itself, or of some neighbouring tumour.

II. Diseases of the lungs or heart, or mediastino-pericarditis, which impede the general venous circulation, may thus lead to ascites. Usually, however, in cases of this kind, the legs are the seat of considerable anasarca before peritoneal dropsy is observed. In course of time the passive congestion causes structural changes in the liver, so that ultimately the ascites may become the most prominent manifestation of the general dropsy.

III. Ascites may constitute a part of the dropsy which so often accompanies renal disease. The amount of intra-peritoneal fluid is, in such cases, generally small.

IV. Effusion into the peritoneal cavity is a usual result of peritonitis, and sometimes occurs so gradually that its inflammatory origin may be at first unsuspected. Moreover, true ascites is observed occasionally as a sequel of peritonitis in consequence of the adhesions or other causes of passive congestion which may occur. Both tuberculosis and malignant disease of the peritoneum may cause ascites in this way.

V. Among the chief *miscellaneous* causes to which ascites has, without much evidence, been attributed are: exposure to cold or wet; the sudden suppression of habitual discharges, or the rapid cure of chronic cutaneous affections; and extreme anæmia and debility. Fluid may collect within the peritoneum as the result of the rupture of a cyst within the abdomen, especially an ovarian cyst.

It must be remembered that ascites may be due to a combination of two or more of the foregoing causes. For instance, portal cirrhosis of the liver may co-exist with mitral incompetence and cardiac failure.

ANATOMICAL CHARACTERS.—The amount of fluid within the peritoneal sac may range from a few ounces to some gallons. Ordinary serous ascitic fluid is generally thin, limpid, and watery in consistence; colourless or slightly yellow; clear and transparent; and of alkaline reaction. In exceptional instances, however, it may be coloured by blood or bile; or more or less turbid and dirty-looking or milky (chylous); or of unusually thick and somewhat gelatinous consistence. Soft fibrinous masses occasionally float in the fluid, or these may form spontaneously when it is allowed to stand. Very rarely the reaction is neutral or acid. The specific gravity varies considerably. Chemically, the fluid contains the same proportion of saline constituents, but a larger proportion of albumen than dropsical fluid from the legs. Occasionally it contains fibrin, cholesterol, bile-elements, or, in cases of renal dropsy, urea.

The fluid will distend the abdominal wall, push up the diaphragm, and compress the rest of the

abdominal contents. There will also be the signs of the morbid condition upon which the ascites depends; and there may also be indications of changes resulting from the long-continued pressure of the fluid.

SYMPTOMS AND SIGNS.—Ascites usually sets in very gradually and advances steadily. Occasionally, however, the fluid collects with considerable rapidity. The clinical phenomena associated with this pathological condition may conveniently be considered under the following heads, namely: 1. *Physical signs.* 2. *Mechanical effects of the dropsical accumulation.* 3. *General symptoms.*

1. *Physical signs.*—(a) If fluid collects in the peritoneum in any quantity, the abdomen presents more or less general enlargement. This is often the first change which attracts the patient's attention, and it may also have been noticed that the increase in size commenced below. The enlargement may be so extreme that the skin is tightly stretched and thinned, presenting a smooth and shining appearance, or sometimes white lines—*lineæ albicantes*—due to laceration of its deeper layers. The umbilicus may be more or less stretched and everted, and finally obliterated, or in some cases pouched out, when it may form a considerable prominence. Should there happen to be a weak portion of the abdominal walls, such as a hernia, this will be unduly protruded. The enlargement is of a rounded form, though tending to be more prominent or to bulge towards the hypogastric region or in the flanks, according to the posture of the patient; it is quite symmetrical in shape, when the patient stands or lies on his back, but alters considerably with a change of position, the abdomen becoming then more prominent in the dependent region, in consequence of the gravitation of the fluid, and this may actually be seen to move as the posture is changed. In contrast with the enlarged abdomen, the chest often looks small and depressed, and the fluid may cause the margin of the ribs to become everted, or it may push forwards the xiphoid cartilage. Mensuration is of service for giving more accurate information as to the size of the abdomen in cases of ascites, and for determining their progress.

(b) The abdomen is perfectly smooth over its entire surface. It usually gives a sensation of tension of the walls, without any hardness underneath. In some instances an obscure feeling of fluctuation is experienced on palpation with the fingers.

(c) The tendency of ascites is to interfere with the abdominal respiratory movements, by preventing the diaphragm from acting properly. At the same time the writer has not uncommonly observed that, even in cases where the accumulation of fluid has been very considerable, abdominal respiration did not seem to be obviously impeded.

(d) *Percussion* affords some of the most important signs of peritoneal dropsy; and when the fluid is present in small quantity this is the only mode of examination that can be relied upon for its detection. In the first place, marked dullness is elicited over the seat of the fluid; while a clear tympanitic sound is heard over the intestines. When there is but little fluid, it may be impossible to detect any abnormal dullness as the patient lies in the recumbent posture; but on placing him on his hands and knees, the fluid gravitates towards the front of the

abdomen, and dulness may then be noticed in the umbilical region. In most cases, however, there is no difficulty in making out the dulness, and when the patient lies on his back, the lower part and sides of the abdomen are dull, while its upper and front part is tympanitic. As more and more fluid collects, so the dulness increases in extent, gathering in, as it were, from below and from the sides, until finally the entire abdomen may be dull, except the umbilical region, which usually remains tympanitic to the last. The boundary line between the dulness and tympanitic sound is usually well defined. As the posture is changed, so will the site of the dulness vary, the part which is undermost presenting this sign, while that which becomes highest is tympanitic, and thus the relative situation of these two sounds, as well as the shape of the dulness, can be altered in a variety of ways. When the patient sits up, the prominence between the recti muscles gives a tympanitic sound on percussion. In exceptional instances a distended colon gives rise to a tympanitic sound along each side of the abdomen, even when there is abundant fluid present.

Another important sign brought out by a form of percussion is the sensation specially termed *fluctuation*, which is the peculiar wave-like movement realised on placing the fingers of one hand over one side of the abdomen, and flipping or tapping the opposite side with the fingers of the other hand. This sensation is very easily brought out if there is much fluid present, provided it is free to move, and sometimes the motion is actually visible. Change of posture will modify the situation over which fluctuation can be produced.

(e) In exceptional instances, when the diagnosis is obscure, it is requisite to resort to a *digital examination* through the *rectum*, and in females through the *vagina*. The fluid collects in the recto-vesical pouch, and on examination *per rectum* the finger detects the sensation yielded by this fluid through its anterior wall. The vagina is usually felt to be shortened, while the uterus is pushed down and flexed. In extreme cases of ascites the posterior wall of the vagina, or even the uterus itself, may protrude through the vulva.

(f) Now and then it is requisite to remove some of the fluid by means of an aspirator or a small trocar, in order to determine its nature. This procedure is also useful when ascites is associated with some other morbid condition within the abdomen, which frequently cannot be made out so long as the fluid remains in the peritoneum.

The ordinary physical signs of ascites will be materially modified or obscured under certain circumstances. For example, the fluid may be so abundant that dulness is observed over the entire abdomen, and fluctuation may be very indistinct. The existence of peritoneal adhesions—for instance, those which may be formed as the result of repeated paracentesis—also renders some of the most characteristic signs of ascites very ill-defined. Again, the association of peritoneal dropsy with some other abdominal morbid condition, such as a new growth, an enlarged liver or spleen, or an ovarian tumour, will also modify the signs elicited. The mesentery may be abnormally short, or the intestines may be adherent, and thus prevented from floating forwards, so that the usual relative positions of dulness and tympanitic sound are not observed.

2. *Mechanical effects of the dropsical accumulation.*—The patient often experiences a feeling of

uneasiness and discomfort in the abdomen, as well as more or less tension and fulness, if there is much fluid present; while there may be a sense of fatigue and aching about the loins or abdominal walls. As a rule no particular pain is felt, but colicky pains are liable to occur from time to time, and extreme distension of the structures constituting the abdominal wall may also cause painful sensations. When the fluid is abundant, the patient is conscious of its weight when he walks; and during progression he throws the head and shoulders back, at the same time keeping the legs apart. Symptoms connected with the alimentary canal are of common occurrence, but these are often to a great extent due to the same cause which originates the ascites, though the fluid must necessarily tend to interfere with the functions of the stomach and intestines. The bowels are usually constipated, but in some instances diarrhoea or dysenteric symptoms may arise. Flatulence is very commonly complained of, even a small amount of gaseous accumulation in the intestines being felt unduly, producing much discomfort, and increasing the enlargement of the abdomen temporarily. Occasionally vomiting occurs, in consequence of interference with the stomach. When a large amount of fluid in the peritoneum presses upon the inferior vena cava, it may lead to anasarca of both lower extremities, with enlargement of the superficial abdominal veins. Exceptionally the anasarca attracts attention at an early period. The flow of blood through the renal veins may also be obstructed, inducing mechanical congestion of the kidneys, with consequent diminution in the quantity of urine and sometimes albuminuria. In rare instances the fluid has been known to accumulate to such an extent as to rupture some part of the abdominal wall.

Ascites also frequently interferes with the thoracic organs. The lungs are more or less compressed and congested, and the breathing becomes chiefly upper-costal, accompanied with various degrees of dyspnoea, and, it may be, cough with frothy expectoration. The heart is likewise liable to be disturbed in its action, as evidenced by palpitation, irregularity, or a tendency to faintness. This organ may also be displaced, so that its apex-beat is too high and too far to the left: in rare instances a basic systolic murmur has been produced by this displacement.

DIAGNOSIS.—The abdominal enlargements from which ascites has to be more commonly distinguished are those due to flabby relaxation of the walls of the abdomen, combined with flatulence; accumulation of fat in the subcutaneous tissue and in the omentum; abundant subcutaneous oedema, which may be associated with and obscure ascites; an ovarian cyst; or a pregnant uterus. Among the more rare conditions with which ascites is liable to be confounded may be mentioned a greatly dilated stomach; colloid disease of the omentum; distension of the uterus with fluid; great accumulation of urine in the bladder; a very large hydatid tumour, usually connected with the liver; extreme cystic enlargement of the kidney; and the so-called 'phantom tumour.' Most of these conditions are described in other parts of this work, and their several diagnostic characters need not be discussed here; but a consideration of the history and existing symptoms of each particular case, and the results of adequate physical and other methods of examination, constitute the data upon which the diagnosis is founded. It must be remembered that ascites

may co-exist with other morbid conditions in the abdomen, their physical signs being then combined. Should there be an enlarged organ or other solid mass, it may often be recognised by making sudden firm pressure with the fingers or *dipping* over the corresponding part of the abdomen, when the fluid is pushed aside, and the underlying resistance can be felt; or paracentesis may be performed, and further examination carried out after the evacuation of the fluid.

Another most important point in the diagnosis of ascites is to make out its cause. If it results from cardiac or renal disease, ascites always follows dropsy in other parts of the body, to which it is also generally subordinate; when it is due to hepatic disease or some neighbouring morbid condition, the peritoneal dropsy appears first, and is, as a rule, throughout most prominent. Should the inferior vena cava be obstructed at its upper part, anasarca of the legs will be observed simultaneously with, or even before, the ascites.

PROGNOSIS.—The prognosis of ascites will mainly depend upon its cause; on the amount of fluid present; on the general nutrition of the patient; on the condition of the principal organs; and on the results of treatment. In some cases ascites is in itself a source of danger on account of the pressure it exerts, especially upon the thoracic organs, and still more if these organs are in a diseased condition. When ascites is due to local interference with the portal circulation, great relief can be afforded and life prolonged by appropriate treatment; while, if the local cause can be removed, the ascites may not infrequently be permanently cured.

TREATMENT.—The principles or treatment applicable to cases of ascites are: (a) to treat the conditions upon which the dropsy depends; (b) to promote absorption of the fluid; (c) to improve the general nutrition; (d) to remove the fluid by operation, if absorption cannot be effected; and (e) to treat any symptoms needing special attention.

(a) The treatment of the causes of ascites is discussed in the articles on the diseases concerned.

(b) Absorption of ascitic fluid is often promoted by acting upon the bowels, skin, or kidneys. In ascites due to local causes, hydragogue and saline purgatives must, however, be administered with caution, and the strength of the patient maintained. In certain instances balsam or resin of copaiba has proved useful as a diuretic in the treatment of peritoneal dropsy. Assistance may be derived from the action of various diaphoretic baths upon the skin. Digitalis and squill may be of service as diuretics; the application of poultices of digitalis leaves over the abdomen is occasionally attended with benefit. The administration of iodide of potassium also seems to aid absorption in some cases, more especially if there be any tendency to syphilitic disease of the liver. It has been recommended to treat ascites merely by a diet of skimmed milk, without any medicine. The application of galvanism to the abdominal walls has been found efficacious in producing absorption of peritoneal dropsy in a few instances.

(c) Treatment directed to the general condition of the patient, and to the state of the blood, is essential in many cases of ascites. Tonics are often of decided service, and preparations of iron are specially indicated for improving the quality of the blood, if there is a tendency to anæmia. Not only

do these remedies sustain the patient, but they may also have an influence in promoting absorption. The diet should be nutritious, and contain but little fluid.

(d) In a considerable proportion of cases, no effect upon the dropsical accumulation is produced by any of the measures thus far considered. It then becomes necessary to determine whether it is desirable to remove the fluid by operation. The fluid may be taken away either by means of the aspirator, by the ordinary trocar and cannula, by Southey's trocars, or by a special apparatus. When ascites is of cardiac or renal origin, the operation can, in the majority of cases, only afford temporary relief, so that there is no object in resorting to it unless the mechanical effects of the accumulation are such as to cause troublesome or dangerous symptoms. When ascites is a local dropsy, the fluid is often so considerable in amount as to necessitate its removal for the mere purpose of giving relief for the time. In cases of ascites associated with malignant disease, for instance, this is all that can be hoped for, as the fluid will certainly collect again. When, however, the condition is due to some local disease which is not in itself fatal, and especially to cirrhosis of the liver, the writer has found signal benefit result from the repeated performance of paracentesis, and has for a long period advocated this plan of treatment as a curative measure, so far as the ascites is concerned. Performed with antiseptic precautions the operation rarely gives rise to any immediate ill-effects, and it is frequently found that remedies will act much more efficiently after the removal of the pressure caused by the fluid than they did previously. In the writer's experience paracentesis, even after one operation, or repeated as often as the fluid re-accumulated, has ultimately led to a complete cure in several instances; in others the cure was partial, a certain quantity of fluid remaining in the peritoneum, limited by adhesions; while in others life has been greatly prolonged, and much comfort afforded. For a few days after the removal of the fluid, the application of a bandage firmly round the abdomen, so as to exert even pressure, may prove of service in aiding the absorption of what remains, and preventing the recurrence of the ascites; and this measure may also be useful when a certain amount of fluid continues after the repeated performance of paracentesis. When the ascites is not cured by repeated tapping, advantage has been found in some instances from allowing the fluid to drain away continuously, or making a free incision.

Operative treatment was introduced in 1896 by Dr. Drummond and Mr. Rutherford Morison, of Newcastle, in cases of ascites from cirrhosis of the liver, having for its object the re-establishment of the portal circulation, by obtaining adhesions between the liver, spleen and omentum, and the parietes. It has since been practised in a few instances, but can only be exceptionally applicable, and is attended with serious dangers.

(e) The symptoms resulting from ascites which are likely to require attention are those connected with the alimentary canal; dyspnœa; and cardiac disturbance, or a syncopal tendency. These should be treated on ordinary principles; but it must be observed that marked dyspnœa or cardiac disorder, if evidently due to the fluid, is an indication for the immediate performance of paracentesis.

FREDERICK T. ROBERTS.

ASEPSIS and ASEPTIC SURGERY.—During the last few years surgeons have been endeavouring to diminish, as far as is compatible with safety, the strength of the antiseptic agents employed during operations and in the dressing of wounds, because it is now recognised that these materials not only increase the amount of exudation, but also diminish the resistance of the tissues to any microbes that may fall into the wounds; in other words, they tend to inhibit the potent antiseptic process of phagocytosis (*see* PHAGOCYTOSIS). There is no doubt that the deleterious effects of these substances upon the epidermis of the surgeon's hands have given a further impetus in this direction; for rough hands are uncomfortable to use and difficult to purify.

Many surgeons, therefore, now repudiate the appellation *antiseptic* and in contradistinction call their method of treatment *aseptic*. This is, however, somewhat of a misnomer, for few, if any of them, dispense with the sterilising of their instruments and dressings by means of the most potent of all antiseptic agencies, namely heat; nor do they neglect the preliminary purification of the skin of the patient, as well as that of the surgeon and of his assistants. They use, however, no germicidal lotions, limiting themselves to boiled water or boiled saline solution, and they employ for dressings only super-heated gauze or cotton-wool. There is more to be said both theoretically and practically for the abandonment of germicidal lotions than for that of antiseptic dressings. The latter have little or no irritating effect upon the wound, the edges of which are usually in contact, and are protected from the dressings by a layer of dried blood or serum; while, on the other hand, should the discharge be sufficiently copious to soak through a simple *aseptic* dressing, there is an obvious danger of the wound becoming infected. It is largely, therefore, a question of convenience. An *aseptic* dressing must be of large size in order to be perfectly safe, and as it is inconvenient in proportion to its bulk, the inconvenience generally outweighs the advantages. Lister himself always taught that *aseptic* surgery was the ideal surgery. During the last few years of his practice he had his sponges wrung out of 1 to 40 carbolic acid solution until they were as dry as possible, and gave up irrigating the wound with this lotion. His results were as good as could be desired.

The description given of an *antiseptic* operation (*see* ANTISEPTIC TREATMENT) applies, with very slight modification, to an *aseptic* one. The skin of the patient is purified with whatever antiseptic agent is in vogue, perhaps with alcohol mixed with 15 per cent. of water, some time before the operation, and is then covered with sterilised gauze until the operation begins. The instruments and swabs are sterilised by boiling. The surgeon's hands are very thoroughly washed with soap and water and subsequently with alcohol (75 per cent.). They are then placed in boiled water or saline solution, and nothing except sterilised water or saline solution comes into contact with the wound during the operation. The dressing is of sterilised gauze or cotton-wool. This method of treatment, in the hands of well-trained and careful surgeons, gives excellent results; but it requires constant attention to the minutest details and is hardly fitted for the exigencies of general practice. The path of wisdom appears to be to use sterilised water or saline solu-

tion during the operation, and afterwards to employ an efficient *antiseptic* dressing.

In abdominal surgery the abandonment of strong lotions has proved of great benefit. The peritoneum is seriously damaged by such solutions, and is thus rendered less able to exert its remarkable power of destroying or subduing the micro-organisms that come in contact with it. There can be no doubt that the abandonment of strong antiseptic solutions has had much to do with the rapid strides that have been made recently in this department of surgery. RICKMAN J. GODLEE.

ASHEVILLE, in North Carolina.—Situated between the Blue Ridge and Alleghany Mountains, in 35° 36' N. lat., 2,250 feet above the sea. A winter and summer resort; of repute in the treatment of phthisis. Temperatures: summer, 70°-7°; winter, minimum has never fallen below 8° F.; range 80°. Rainfall, 40 inches. Possesses a sanatorium. *See* CLIMATE, Treatment of Disease by.

ASIATIC CHOLERA.—*See* CHOLERA, ASIATIC.

ASPHYXIA (ἀ, priv.; and σφύξις, pulse).—*SYNON.*: Apnoea; Fr. *Asphyxie*; Ger. *Erstickung*.

DEFINITION.—The term *asphyxia*, though literally signifying *pulselessness*, is generally understood to mean the condition that supervenes on interruption of the function of respiration. The term *apnoea*, formerly suggested as a more exact one, is now definitely employed by physiologists in a totally different sense, viz. the cessation of the respiratory movements consequent on artificial hyperoxygenation of the blood.

ÆTIOLOGY.—Asphyxia may result from many causes which obstruct or interrupt the respiration. They may be divided into two categories, internal and external.

Internal.—These include paralysis of the respiratory nerve-centres by disease or injury of the medulla oblongata; paralysis of the nerves or muscles of respiration; a rigid fixation of the respiratory muscles; collapse or disease of the lungs; occlusion of the air-passages by organic disease or spasm of the glottis, pressure of tumours, and the like.

External.—To this group belong occlusion of the air-passages by foreign bodies; pressure on the chest not capable of being overcome by the muscles of respiration; closure of, or external pressure on, the air-passages, as in suffocation, strangulation, or hanging. To these external causes are to be added those conditions in which, though the respiratory movements are free, the surrounding medium is incapable of oxygenating the blood, viz. submersion in a liquid medium (drowning); or being surrounded by a medium devoid of oxygen, such as nitrogen or hydrogen. These gases have a purely negative effect; but many other gases which are classed as asphyxiants, such as carbonic oxide, sulphuretted hydrogen, chlorine, chloroform-vapour, &c., have positive poisonous effects, and should therefore be called by some special name, such as *toxic asphyxiants*, to distinguish them from those which have no such properties.

PHENOMENA.—The phenomena of asphyxia have been studied (1) by placing animals in an atmosphere devoid of oxygen, and (2) by suddenly obstructing the trachea (slow and rapid asphyxia respectively). The results, substantially the same, may be divided into three stages, the first being marked by increased respiratory movements, both of inspiration and

expiration. The second is characterised by increased expiratory efforts and general convulsions. In these two stages the blood-pressure rises. In the third stage the blood-pressure falls, the reflexes are abolished, insensibility sets in, and the inspiratory efforts are long drawn out and finally cease. The failure of respiration is followed after a time by that of the circulation, the heart stopping in diastole. Though the time required for producing complete asphyxia varies to some extent in different animals and in the same animal under different conditions, death from rapid asphyxia takes place usually in four or five minutes after complete obstruction of the trachea.

PATHOLOGY.—The presence of non-oxygenated blood in the vessels by stimulating the respiratory centre causes increased respiratory efforts, and by irritating the vaso-motor centre induces contraction of the arteries. In consequence, the blood-pressure rises and the cardiac cavities become more and more distended. The distension finally becomes so great that the heart is unable to cope with the accumulation of poisoned blood, the cardiac movements become slow and feeble, the blood-pressure falls, and finally the heart ceases to beat.

In the production of asphyxia two chief factors must be considered, namely the deprivation of oxygen and the accumulation of carbonic acid; but it is to the deficiency of oxygen rather than to the excess of carbonic acid that the phenomena of asphyxia are to be ascribed, for it has been shown that if an animal be placed in an inert atmosphere (nitrogen) all the phenomena of asphyxia ensue, though there is no impediment to the exit of carbonic acid. On the other hand, when an animal is made to inhale an atmosphere containing both an excess of carbonic acid and plenty of oxygen, the effects resemble those of a narcotic poison; there is laboured and increased frequency of breathing but no convulsions. Practically, therefore, under experimental conditions asphyxia is tantamount to deprivation of oxygen, but in clinical and medico-legal practice it is rare to meet with instances of such pure asphyxia. The cases designated as asphyxia are really combinations in varying degree of the two conditions (asphyxia and carbonic acid poisoning), and very often the toxic effects of carbonic acid cannot be considered to hold a subordinate place.

ANATOMICAL CHARACTERS.—The blood is of a dark colour, owing to complete reduction of the hæmoglobin. The proportion of carbonic acid is increased, and owing to its excess the blood coagulates slowly or imperfectly; hence it remains fluid or forms few and soft coagula. The large veins, the pulmonary artery, and the cavities of the right side of the heart may be distended with dark fluid blood, but this is by no means necessarily the case. The left side is usually empty or nearly so. The lungs may be congested, but are often pallid and anæmic, though the dependent parts usually exhibit appearances of hypostatic engorgement. The abdominal viscera, especially the kidneys, are often congested. The appearance of the brain varies; it may be anæmic or more or less congested. Special signs characterise special modes of causation of asphyxia.

TREATMENT.—Resuscitation from pure asphyxia is possible so long as the heart continues to beat. After cessation of the heart's action treatment is unavailing, except in cases of cessation from mere

over-distension, in which bleeding from the external jugular vein may be resorted to with success. The chief indication in the treatment of asphyxia is to effect oxygenation of the blood by the introduction of air into the lungs. See **ARTIFICIAL RESPIRATION**; and **RESUSCITATION**.

ASPHYXIA, Local.—A synonym for Raynaud's Disease. See **RAYNAUD'S DISEASE**.

ASPIRATOR.—See **PARACENTESIS**.

ASPIRATOR.—**SYNON.**: Fr. *Aspirateur*.

DESCRIPTION AND MODE OF EMPLOYMENT.—There are two forms of 'aspirator' in common use. (1) That designed by Dieulafoy in 1869 consists of a glass syringe, with a capacity of one to four fluid ounces, having at its lower end two openings provided with stopcocks. If the piston is raised after the cocks are closed, a vacuum is created in the syringe, which can be maintained by fixing the piston in the withdrawn position. An india-rubber tube is fitted into each of the two openings, and these tubes are provided with coils of wire inside to prevent them from collapsing. At the end of one tube is fixed a fine hollow needle. The needle should have only one opening, at the point. The instrument is thus used:—A vacuum having been created in the syringe, the needle is introduced into the part to be operated upon. As soon as the opening of the needle is beneath the skin the stopcock leading to it must be opened. The vacuum will then extend to the point of the needle; and consequently, if it be gently pushed onwards, the moment it encounters fluid this will jet up into the glass syringe, when its nature may be ascertained. In aspiration thus performed it is impossible to pass the needle through a collection of fluid without discovering it. If the fluid is sufficient in amount to fill the syringe, the stopcock leading to the needle is to be closed and the other opened: by this the fluid may be discharged. The vacuum may then be re-established, and the operation repeated as often as is necessary. The aspirator may be converted into a siphon by opening both stopcocks when the syringe is full, and allowing the discharge-tube to hang down. The action of the instrument may also be reversed, and it may be thus employed for injecting fluids. (2) In Potain's aspirator the receiver is a glass bottle, from which the air is exhausted by means of an attached air-pump. An objection to this is that, if the needle becomes choked, it cannot be cleared by pushing down the piston and driving some of the fluid back through it; but it has the advantage of being less liable to get out of order, as the fluid does not touch the exhausting syringe. The disadvantage can be avoided by the use of an attached trocar and cannula, but this modification is suitable only when the exact locality of the fluid is known, for the instrument is thereby converted into a mere 'suction-trocar.' The needles employed vary in size. Dieulafoy recommends that they should be about $\frac{1}{10}$, $\frac{1}{20}$, $\frac{3}{20}$, and $\frac{1}{12}$ of an inch in diameter, and calls them Nos. 1, 2, 3, and 4 respectively.

The following rules must always be observed in using the aspirator:—1st. See that the skin is thoroughly cleansed (see **ASEPSIS**), the needle pervious and clean, and the syringe in order before using it. It is advisable to boil the needle before use. Any parts made of platinum can be

sterilised by heating over a spirit lamp. 2nd. The needle must be pushed straight on in one direction only. Its course should not be altered while the point is under the skin. If no fluid is found, it may be withdrawn and reinserted. It must be held as steady as possible during the aspiration. 3rd. If the fluid will not flow with the pressure of the atmosphere, it is of no use squeezing and pressing the part. This can only do harm. 4th. Aspiration must cease at once when blood comes in any quantity, especially in abscesses. 5th. Keep up the vacuum during the withdrawal of the needle, lest some of the morbid fluid be left in its track. 6th. If the needle becomes choked, force a little of the fluid back through it in order to clear it. In Potain's instrument the trocar can be re-inserted. 7th. After use the whole apparatus must be thoroughly cleaned with plain water for completely removing pus, blood, and other albuminous fluids, which would be coagulated by carbolic acid. After this is thoroughly done, the needle, tubes, and syringe should be disinfected by boiling. *See ASEPSIS.*

USES.—Aspiration is used for purposes of diagnosis and treatment. Dieulafoy asserts that with the No. 1 needle it is possible to search for fluid without danger, whatever may be its seat or its nature; and experience has proved this to be practically true. In treatment it has been employed in the following affections, but is now much less used than formerly, owing to the marked diminution in the risk of septic contamination of open incisions, and the proved necessity either for continuing the drainage of a cavity from which fluid has been withdrawn, or for combining other surgical procedures with the removal of the morbid fluid.

Abscesses.—In acute abscesses simple aspiration is usually of little value, as the pus soon re-accumulates. In chronic abscesses connected with diseased bone it usually fails, and is often impracticable, from the presence of cheesy masses in the pus. If performed with proper antiseptic precautions, however, it can do no harm, and may, if repeated, diminish the size of the sac before other means are adopted, or even effect a cure. Instead of the small needle, a large trocar, from $\frac{1}{8}$ to $\frac{1}{4}$ inch in diameter, is fitted to the aspirator. If necessary a small incision is made in the skin to facilitate the introduction of the trocar. The abscess having been emptied of its contents, the cavity is distended with a solution of perchloride (1 in 4,000), or of biniodide (1 in 5,000) of mercury, which is also withdrawn by the aspirator. This must be repeated again and again, till the fluid returns perfectly clear. Finally, an emulsion of iodoform and glycerine (1 in 10) is injected, the trocar is withdrawn, and the opening sealed with collodion. Most commonly the abscess fills again in a few days, after which the fluid may be gradually absorbed, but it is frequently necessary to repeat the operation more than once. The method has often to be supplemented by that of free drainage.

Diseases of the Liver.—Hydatid cysts were formerly treated by aspiration. *See PARACENTESIS.*

Retention of Urine may be safely relieved by using No. 2 needle above the pubes; but great care must be taken that the needle is sharp as well as clean.

Diseases of Joints.—Aspiration is occasionally useful in acute synovitis, especially of the knee-joint (*see JOINTS, Diseases of*). No. 1 or 2 needle should be used. *Spina bifida* is occasionally

treated by aspiration, with or without the subsequent injection of Morton's fluid. In *Pleurisy* accompanied by serous exudation, aspiration is frequently employed (*see PLEURA, Diseases of; and PARACENTESIS*). In *Ascites*, except for purposes of diagnosis, the aspirator presents no advantages over a trocar properly constructed so as to exclude air (*see PARACENTESIS*). *Pericarditis.*—The operation of aspiration has frequently been successfully performed for grave pericardial effusion. It is thus carried out:—A spot is chosen 2 to 2½ in. beyond the left edge of the sternum, in the 4th or 5th interspace. No. 2 needle is then passed obliquely upwards and inwards, care being taken to turn on the vacuum as soon as the eye is covered. The moment the fluid jets into the syringe the needle must be held steadily till the flow ceases. If this be done there is no danger of wounding the heart. If there is any doubt as to the existence of fluid, No. 1 needle must be employed, with which the heart may be punctured without great danger.

FRED. C. WALLIS.

ASTHENIA } (ἀ, priv. ; and σθένος, strength).—
ASTHENIC }

Terms signifying want of strength. As applied to the entire system, they indicate considerable general debility; in connection with particular diseases, they imply that these are attended with marked weakness. *See DEBILITY.*

ASTHENOPIA (ἀ, priv. ; σθένος, strength ; and ὤψ, the eye).—Weakness of sight. *See VISION, Disorders of.*

ASTHMA, SPASMODIC (ἄσθμα, panting ; from ἄω, I blow).—**SYNON.** : Bronchial asthma ; Fr. *Asthme* ; Ger. *Bronchial-Asthma*.

DEFINITION.—An affection characterised by severe paroxysmal dyspnoea recurring at more or less definite periods, generally in the night, the dyspnoea being due to spasmodic contraction of the bronchi, produced by a variety of causes.

ÆTIOLOGY.—The causes that induce an attack of asthma are very various, and may be roughly classed according to their action, *direct* or *indirect*, on the respiratory organs. In the former class the exciting cause immediately affects the mucous membrane ; in the latter it does so in a more circuitous manner, generally through the blood or the nervous system :—

Direct	{	Dust.
		Vegetable irritants.
		Chemical vapours.
		Animal emanations.
Indirect	{	Climatic influences.
		Bronchial inflammation.
		Through the nervous system.
		Through the blood
	{	Centric.
		Excito-motor.
		Gout.
		Syphilis.
Heredity.	{	Skin-diseases.
		Renal diseases.

Direct causes.—Common roadside dust ; fluff from woollen clothing ; the dust of mills, threshing-floors, or bakehouses ; and any mechanical particles when inspired, will produce in some persons an asthmatic seizure ; dust of low specific gravity being more apt to have this effect than heavy particles like coal, steel-filings, &c., from which arise lesions in the lung of a more permanent and serious character.

The odour evolved by certain vegetables, such as

ipecacuanha; the pollen of many grasses and plants (see HAY-FEVER); certain chemical vapours, as that of pitch, sulphurous acid, and phosphorus-fumes; the peculiar smell of some animals, as dogs, cats, horses, and hares, may each provoke a spasm in individual cases.

A still more powerful cause is climatic influence, the action of which on different patients cannot, unfortunately, be reduced within the limits of a law, but depends mainly on the idiosyncrasy of the individual. Extremes of temperature, or excessive dryness or dampness, may produce an asthmatic seizure, but in the largest number of cases one of two elements appears as the chief factor. One large class of sufferers trace the attack to *dampness*, whether of soil or of atmosphere, in combination with either heat or cold; another to *closeness* of atmosphere and a want of proper circulation of air, such as is found in deep valleys and thick forests, and during thundery weather—this last class experiencing great relief when a breeze springs up. Malaria plays an important part occasionally in the causation of asthma.

Far more general and intelligible in its action is *bronchial inflammation*, which is the cause in 80 per cent. of asthmatic cases. It frequently happens that after whooping-cough, measles, or infantile bronchitis the tendency towards asthma begins to appear. These diseases, implicating as they do both bronchial muscle and nerve supplying it, leave their mark behind, either in irritability of the mucous membrane; in induration of some portion of the lung, generally at the root; or in enlargement of the bronchial glands, causing pressure on the pneumogastrics, or on some of the branches of the pulmonary plexuses (see BRONCHIAL GLANDS, Diseases of); and thus lay the foundation of asthma in after-life. Asthma following on arrested phthisis is not rare in adults, probably from enlargement of the bronchial glands. In other instances the indirect cause may be found in morbid states of the nose or throat.

Indirect causes.—This class of causes includes those acting through the general nervous system; those acting through the blood; as well as the hereditary influences.

The *centric* subdivision embraces attacks arising from emotion, anger, or fright; as well as the curious alternations of asthma, neuralgia, angina, and gastralgia due to some centric irritation in the medulla, involving the origins of the fifth and eighth pairs of nerves, and manifesting itself by affecting first one branch and then another of these nerves.

Excito-motor causes may be illustrated by indigestion or costive bowels giving rise to a paroxysm of asthma. In the first case, irritation of the medulla is induced through the gastric branches of the pneumogastric, and a motor effect is reflected through the pulmonary branches. These *peptic* attacks, as they are called, occur more frequently after suppers than dinners, probably because reflex irritability is always exalted by sleep, as we know to be the case in epilepsy and the convulsions of childhood.

Gout, towards old age, often takes the form of asthmatic seizures, which alternate with the articular affections. In like manner attacks of the disease have been attributed to syphilis, but here the poison generally acts by enlarging the bronchial glands.

The connection between asthma and various kinds of skin-disease is intimate: the subsidence of eczema, of urticaria, or of psoriasis, has often been accompanied by fits of spasmodic breathing, which have

ceased on the reappearance of the eruptions. Here, again, the state of the blood is presumed to be the origin of both maladies, as in disease of the kidneys, which will be presently referred to.

Heredity can be traced in about 40 per cent. of asthmatics, though the tendency often does not show itself till late in life. The characteristic form of chest is frequently transmitted from parents to children; and even when this is not so, a disposition towards spasmodic symptoms in catarrhal attacks is often seen in the children of some asthmatics.

SYMPTOMS.—The patient may retire to bed with few or no premonitory symptoms, and sleep for some hours, but is disturbed in the late night or early morning—2 A.M. is a common time—by a feeling of oppression approaching to suffocation, referred either to the throat, sternum, or epigastrium, which obliges him to sit up in order to breathe. Sometimes the onset is more gradual: the patient, having fallen asleep in spite of uneasy sensations, begins to wheeze during sleep, and is only aroused when the dyspnoea becomes severe. The breathing is accompanied by a humming sound, which gradually develops into a great variety of discordant noises.

In order to increase the capacity of his chest to the utmost, the asthmatic patient sits up and fixes his shoulders, either by placing his hands on either side of him, or by supporting his elbows on his knees; or sometimes he stands leaning over the back of a chair or other support. In one or other of these positions he remains immovable, with chest, back, shoulders, and head fixed; unable to speak or even to move his head; the lips being parted; the face pale, anxious, and, if the dyspnoea continue, livid; and the eyes prominent and watery. Every muscle of respiration, ordinary and extraordinary, is brought into requisition; those passing from the head to the shoulders, to the clavicles, and to the ribs become rigid, and, in place of moving the head and neck, act the reverse way, being used from fixed points to raise and dilate the thorax. The trapezii and levatores anguli scapulae by their contraction elevate the shoulders, in order that the muscles connecting these with the ribs may act as elevators to the latter. Even the muscles of the back are pressed into the service, and they almost cease to support the back; consequently the patient stoops. At each inspiration the sterno-cleido-mastoids stand out like cords, leaving a deep hollow between their sternal attachments; the diaphragm is contracted, and hence the stomach, liver, and heart are somewhat displaced. With all this display of muscular force, the chest remains almost motionless, being expanded to a variable extent.

In spite of the great dyspnoea, respirations are not proportionately frequent, seldom exceeding thirty, and sometimes falling to nine a minute. The expiration is prolonged, being generally two or three times as long as the inspiration. The pulse is usually slow and feeble; the temperature rarely exceeds 99° F., and is often below 98° F. Analysis of the expired air shows the oxygen to be almost entirely replaced by carbonic acid, which may increase from the normal to as much as 11 per cent., the nitrogen varying from 89 to 93 per cent. The arrest of expiration is probably the cause of the accumulated carbonic acid, but the total disappearance of the oxygen is hardly to be explained, for that oxidation of the tissues does not proceed is shown by the pale urine passed after the fit.

PHYSICAL SIGNS.—These reveal less than might be expected. The percussion-note is somewhat raised over the whole chest, most so in the posterior regions, where a drum-like sound occasionally prevails; this hyper-resonance is probably due to accumulation of air induced by obstructed expiration, and in incipient cases passes off with the attack. The normal areas of cardiac and hepatic dullness often disappear during the attack, owing to the emphysema temporarily induced. When the attack has passed off, careful examination will sometimes detect dullness in the supra-scapular or inter-scapular regions, on one or both sides of the chest, indicating probable enlargement of the bronchial glands.

Auscultation shows an entire abolition of the normal breath-sounds, and the existence of dry sibilant or sonorous rhonchi everywhere, varying in tone according to the calibre of the bronchial tubes; the smaller tubes giving the high notes, and the larger ones the deep notes. These sounds continually change their position, springing up under the listening ear, and as quickly vanishing again, to give place to profound silence.

PROGRESS AND DURATION.—A paroxysm of asthma, when once established, lasts from half an hour to several days, and generally terminates with expectation—thin and transparent if the seizure be short; but abundant and more or less opaque if the fit be prolonged, or if the case be chronic. The sputum has also been found to contain, in greatest abundance at the close of the attack, (1) the so-called Charcot-Leyden crystals, which are minute octahedra of unknown composition, but soluble in warm water; (2) Curschmann's spirals, which consist of closely packed epithelial cells, arranged in a spiral form surrounded by mucoid material; and (3) a large number of eosinophile cells. None of these are, however, pathognomonic of asthma. The urine is light-coloured and plentiful; the skin is bathed with perspiration; and flatus is often expelled from the bowels. Little or no food is taken during the attack, at the close of which the patient falls asleep.

The recurrence of the attacks when once they have been excited is generally periodic; but much depends on the presence or absence of the exciting cause. In many cases the patient is quite free from wheezing and dyspnoea in the intervals, and feels and acts like other people; but when the attacks follow each other closely, a more or less wheezy condition remains behind, and a few signs of obstructed breathing are generally to be detected in the inter-scapular regions.

COMPLICATIONS AND SEQUELÆ.—If the asthmatic attacks become habitual, their effects are seen on the patient's frame and on the organs implicated. The shoulders become raised, the head being buried between them; the muscles of the back, owing to their being called on to act as extraordinary muscles of respiration, are diverted from their use as erectors of the spine, which, accordingly, yields in the anterior direction, and the patient stoops. The frequent occurrence of spasmodic contraction of the bronchi causes hypertrophy of their muscular coat; and this, with or without the congestion of the mucous membrane accompanying it, leads in time to thickening of the tubes and permanent narrowing of their calibre. The more common result of asthma is emphysema, arising from the difficulty of expiration. The emphysema, at first temporary, becomes in chronic cases permanent, and gives rise

to displacement of the adjoining organs (*see EMPHYSEMA*). Contraction of the bronchi largely influences the pulmonary vessels, and considerable obstruction of the pulmonary circulation is the result. The vessels become gorged, and the lungs sometimes cedematous. If the emphysema be extensive, we may in time expect dilatation of the right side of the heart and marked prominence of the veins of the breast and neck, and the effects may be carried so far as to cause oedema of the lower extremities and albuminous urine, as the writer witnessed in a case where these symptoms disappeared on the subsidence of the asthma.

PATHOLOGY.—Patients rarely, if ever, die of spasmodic asthma, though death may ensue from some of its complications and sequelæ; and the disease, being a functional one, cannot be said to have any morbid anatomy. The onset and departure of the attack, and the ever-changing physical signs, led Laennec to think that whatever obstruction in the bronchial tubes caused the phenomena must be of a spasmodic and transitory nature. He therefore concluded that asthma was due to a spasm of the bronchial muscles which had been described by Reisseissen. Laennec also showed that an asthmatic sufferer could sometimes, after holding his breath, actually breathe naturally for one or two respirations, thus clearly demonstrating that the spasm was capable of momentary relaxation. Other theories were put forward, and doubt was thrown on the existence of muscular fibres in the bronchi, until Dr. C. J. B. Williams proved their existence by his experiments on the lungs of oxen, dogs, rabbits, and other animals, when he caused contraction of the trachea and bronchial tubes by the application of electrical, chemical, and mechanical stimuli. The muscular coat was shown to be more abundant in the smaller tubes than in the larger, the former contracting sufficiently to obliterate their passages entirely. In asthma, excitation of the muscles probably takes place through the anterior and posterior pulmonary plexuses, which are made up of branches from the pneumogastric, recurrent laryngeal, and spinal nerves, and from the ganglia of the sympathetic, thus giving the bronchial tubes a very wide area of connections. The branches of the pulmonary plexus form a network round the bronchial tubes, and contain some minute ganglia. When the cause is direct, as dust of any kind or climatic influence, the spasm may be induced by reflex action through these small ganglia, or through the pulmonary plexus, though it soon extends, involving the pneumogastrics, and affecting the thoracic muscles through the upper cervical, phrenic, and dorsal nerves. Where emotion, fright, or laughter starts the fit, the irritation is centric, and causes a motor effect on the pulmonary plexus through the pneumogastrics. Where, again, indigestion excites it, the sensation passes through the gastric branches of the pneumogastric, and is reflected by the motor filaments of the pulmonary plexus. Lastly, where gout, syphilis, albuminuria, skin-disease, and heredity are the excitants, we may regard the blood itself as causing the local irritation. Spasmodic asthma may, therefore, be considered as a neurosis of the pulmonary branches of the plexus of that name similar to other neuroses, as hemicrania and sciatica, and giving rise, through the motor nerves of the plexus, to spasm of the bronchial muscle. *See also BRONCHIAL GLANDS*; and *BLOOD, Morbid Conditions of*.

DIAGNOSIS.—Asthma is distinguished from *bronchitis* by the fugitive physical signs; by the spasmodic character of the dyspnoea; and by the scant expectoration. The breathing in bronchitis, when at all difficult, is hurried; in asthma it is slow, wheezy, and prolonged; this feature also contrasting strongly with the gasping, panting dyspnoea generally accompanying pneumonia, pleurisy, and some forms of heart-disease. From *croup* it is recognised partially, but not entirely, by the age of the patient; and partly by the character of the dyspnoea, which in croup is inspiratory, whereas in asthma it is mainly expiratory. This characteristic also distinguishes asthma from spasm of the glottis and the various forms of laryngeal dyspnoea. The diagnosis from *emphysema*, which is so often mixed up with spasmodic asthma, is founded chiefly on the paroxysmal character and violence of the asthmatic dyspnoea, and on the complete freedom of the intervals, the dyspnoea of emphysema being more or less permanent.

Aneurysm of the aorta and other *mediastinal tumours* often give rise to symptoms so exactly simulating spasmodic asthma as to make the diagnosis difficult, and this is to be accounted for by these tumours pressing on the pneumogastric nerve and its branches, and thus inducing an asthmatic spasm. These cases are, as a rule, however, accompanied by a certain amount of stridor arising from laryngeal spasm, not present in asthma, and this symptom is often of great diagnostic value in obscure cases. As the tumour enlarges, it causes greater pressure on the lungs, trachea, œsophagus, sympathetic ganglia, or other structures, and produces shrill cough, dysphagia, difficulty of inspiration, pain in the chest, impulse in the thoracic wall, and other well-known aneurysmal symptoms. Moreover, certain physical signs become evident, e.g. dulness over the first portion of the sternum or to the right of it, or between the scapulae; tubular sounds and bronchophony close to the sternum, or above one or both scapulae; or some form of bruit or murmur in the course of the aorta. These and other symptoms and signs contrast sufficiently with those of spasmodic asthma to make the diagnosis from developed aneurysm comparatively easy.

In some cases of *renal disease* in which albumen appears in the urine, a form of dyspnoea appears, which is occasionally marked by paroxysmal features, and has been mistaken for spasmodic asthma. Renal dyspnoea differs, however, as a rule, in being more continuous, and in having for its origin œdema of the lung rather than bronchial spasm. See **RESPIRATION, Disorders of.**

PROGNOSIS.—The question of recovery in cases of asthma depends, to a certain extent: first, on the possibility of the removal of the exciting cause; secondly, on the age of the patient; thirdly, on whether the attacks increase or not in frequency; fourthly, on the condition of the lungs and the breathing in the intervals.

If the patient be young (say, under fifteen), the chest well formed, the attacks tending to diminish in frequency and intensity, and the lungs free in the interval, a most hopeful prognosis can be given. If, on the other hand, the patient be middle-aged, the attacks increasing in number and severity, and the breathing more or less short in the intervals, we may conclude that there exists a considerable amount of permanent emphysema, which renders the prognosis of an unfavourable character. In every

instance the detection and removal of the exciting cause or causes, as the case may be, exercise a chief influence over the prognosis.

TREATMENT.—The principal difficulty in the treatment of asthma lies in clearly ascertaining the nature and origin of the exciting cause. When this is discovered two great principles should guide us, namely: first, to avoid or remove the exciting cause; secondly, to allay and prevent the spasm.

Many of the cases arising from direct causes, as from dust and chemical vapours, are cured by simple avoidance of the exciting cause. Where bronchial inflammation induces the spasm, the inflammation must be subdued by salines and expectorants, combined with some anti-spasmodic, as belladonna, henbane, or stramonium. In more chronic instances, where some thickening of the walls of the larger bronchi and enlargement of the bronchial glands exist, iodide of potassium in doses of grs. v. to xv., or iodide of sodium in doses of grs. v., or a combination of both iodides, has been found very beneficial when persisted in for long periods. Symptoms of iodism may be generally averted by temporarily diminishing the dose and diluting more largely with water. The waters of Woodhall and Purton in England, of Kreuznach in Germany, of Saxon in Switzerland, and Salsomaggiore in Italy, contain iodides largely diluted, and may be beneficially administered in asthma. Affections of the nose or throat will require attention (see **NOSE, Diseases of**). Where the attacks depend on gout, syphilis, or renal disease, or are connected with skin-disease, treatment must be directed to the condition of the blood. Arsenic proves of signal service in asthma co-existing with eczema, psoriasis, or other skin-affections.

Where heredity is the predisposing cause, the origin of the disease lies generally in defective development of the frame or of the lung-structure of the patient. For such persons gymnastic exercises, carefully conducted swinging on the trapeze, and other means of expanding the upper part of the chest and correcting the asthmatic stoop are to be employed, combined with tepid or cold sponging and as much outdoor life as possible, with walking and riding without fatigue. The tendency to catarrh is thus lessened, and the frame of the patient developed and fortified. In a large number of cases—as, for instance, those arising from climatic influences—we have to treat a simple neurosis, and to allay the spasm either by climatic or by medicinal means, of which the former is often the more important, and, owing to the leading part played by the idiosyncrasy of the patient, generally the most difficult. In obstinate cases the doctrine of contrasts appears the only safe one. Where the disease has been contracted in a moist climate, a dry one must be tried; if in an inland district, the seaside must be resorted to; but for by far the majority of asthmatics the atmosphere of large towns is suitable and the smokier the air and the closer the streets the more good do the sufferers appear to receive. London, Glasgow, Birmingham, and Bristol are all favourable resorts for cases of neurotic asthma; and the points of difference between their atmospheres and that of the country consist (1) in greater dryness; in deficiency of oxygen; and (3) in excess of carbonic acid and carbon: all of which peculiarities appear to exercise a sedative effect on the neurosis. Damp, whether of soil or

atmosphere, is usually found to be hurtful, and is one of the chief exciting causes of asthma. Nothing exemplifies this more completely than the excellent results in cases of asthma produced by climates of which the atmosphere is dry.

The medicines most useful in asthmatic attacks are antispasmodics, either stimulant or sedative. The former, including alcohol, strong coffee, nitroglycerine, ether, and nitrite of amyl, will prove more efficacious where emphysema is present; the sedative comprise stramonium, belladonna, Indian hemp, lobelia, *Datura tatula*, tobacco, opium with its alkaloids, and drugs of a similar action. These may be taken internally in the form of extracts or tinctures; or smoked in pipes or as cigarettes; or inhaled as vapour diffused through the room by burning powders or pastilles containing them. A popular and often reliable remedy is the vapour arising from the combustion of nitre-paper, and other useful forms of powder may be devised; but these should be recommended with caution, lest an unfortunate habit of indulgence in fuming preparations be acquired. In the severest attacks the patient can neither smoke nor swallow, and in this difficulty of introducing medicines into his system we find the hypodermic injection of atropine (gr. $\frac{1}{100}$), morphine (gr. $\frac{1}{4}$ – $\frac{3}{4}$), and chloral hydrate, or suppositories of morphine and belladonna, prove effectual; but if albuminuria or emphysema be present, or if the pulse be weak, they must not be used. Chloroform often acts like a charm in the worst cases, and after inhaling 20 to 60 minims the patient will gain the sleep which has been denied to him for hours or even days; but as the effect is generally transitory, and the use of the remedy not free from risk, it should be given, if at all, in capsules containing a measured dose. Iodide of ethyl (m. v.-x.) can be inhaled with advantage. Ether is safer, but not so effective. Chloral hydrate in doses of 15 to 20 grs., repeated every four hours until the spasm subsides, has produced not only temporary but even permanent good in a large number of asthmatic cases, and, if watched, may be persisted in for some time. In the writer's hands it has proved a most successful remedy. In the use of antispasmodics we must avoid judging the effects of one from the failure of another of the same class; but in difficult cases we must try each in succession—for it often happens that the successful remedy is only arrived at after repeated trials.

The mineral waters of Mont Dore and La Bourboule contain arsenic, and appear to act favourably in the more purely neurotic cases of asthma, while those of the Pyrenean sulphur springs of Eaux Bonnes, Eaux Chaudes, and Cauterets, are reputed to exercise a beneficial influence over the malady, but they have not been successful in the writer's experience, and it is more probable that they relieve by reducing the catarrhal symptoms than that they either allay the spasm or prevent its recurrence.

Compressed-air baths at pressures varying from one and a half to one and two thirds of an atmosphere, and lasting two hours, are of the greatest benefit to asthmatics, and appear to reduce the sensitiveness of the pulmonary plexus and to diminish cough and spasm, but they must be taken in numbers varying from 24 to 50 to be of permanent value. See AIR, Therapeutic Use of.

The dietetic treatment varies in individual cases, but as a rule asthmatics should dine early, and for the rest of the day limit themselves to liquid food,

such as beef-tea, soups, and milk, combined with such an amount of stimulant, in the form of a pure spirit, as may be necessary, thus avoiding any distension of the stomach and intestines before retiring to rest. The diet should consist of brown bread, dry toast, and biscuits—excess of starch in any form being studiously avoided—a fair supply of plainly cooked meat, fish, or poultry, and a limited amount of vegetables and fruit, care being taken to select only the most digestible of each class. Stimulants may sometimes be taken, but with discernment.

C. THEODORE WILLIAMS.

ASTIGMATISM (ἀ, priv.; and *στίγμα*, a spot or point).—SYNON.: Astigmism.—Want of symmetry in the anterior refracting surfaces of the eyeball, in consequence of which rays of light proceeding from a point are not brought to a focus upon the retina as a point, but only as a diffused spot. See VISION, Disorders of.

ASTRINGENTS.—DEFINITION.—Medicines which cause contraction of tissues.

ENUMERATION.—The chief astringents are: Nitrate of Silver; Sulphate of Copper; Sulphate of Zinc; Acetate of Lead; Perchloride of Iron; Alum; Tannic and Gallic Acids, and vegetable substances containing them, such as Oak Bark, Galls, Kino, and Catechu; and Dilute Mineral Acids. Some authors also include in this class of remedial agents such articles as Ergot of Rye, which contracts the blood-vessels and lessens hæmorrhage after it has been absorbed into the blood, although it has no local astringent action.

ACTION.—With the exception of gallic acid, the substances already mentioned coagulate or precipitate albumen. Dilute mineral acids do not coagulate albumen, but precipitate many albuminous bodies from the alkaline fluids by which they are held in solution. When applied to a surface from which the epidermis has been removed, the other astringents combine with the albuminous juices which moisten this surface, as well as with the tissues themselves, and form a pellicle more or less thick and dense, which in some measure protects the structures beneath it from external irritation, at the same time that they cause the structures themselves to become smaller and more dense. On a mucous membrane they have a similar action, and they lessen its secretion. It was formerly supposed that their action was partly due to their causing the blood-vessels going to a part of the body to contract, thus lessening the supply of fluid to it; as well as to their effect on the tissues themselves. But experiment has shown that, while nitrate of silver and acetate of lead possess this power, perchloride of iron and alum do not, and that tannic and gallic acids actually dilate the vessels. The astringent action of these latter drugs must therefore be exerted upon the tissues.

USES.—Astringents may be employed locally in various forms. In the solid form, as a powder, or in various preparations such as lotions, ointments, plasters, and glycerines, they are applied, especially the metallic astringents, to wounds and ulcers for the purpose of reducing the size and increasing the firmness of exuberant granulations, as well as of protecting the surface by forming a pellicle over it. They are used to lessen congestion and diminish the secretion of the various mucous membranes: as a lotion to the eye and mouth; as a

gargle or a spray to the throat ; in the form of an injection to the nose, urethra, and vagina ; and as a suppository to the rectum. Administered internally, several astringents have a powerful effect in checking diarrhoea, and certain of them may have a local action upon the stomach and intestines.

The *remote* action of such astringents as acetate of lead and gallic acid, when absorbed into the blood, in lessening hemorrhage, is made available in the treatment of hæmoptysis, hæmatemesis, hæmaturia, and loss of blood from other parts of the body.

T. LAUDER BRUNTON.

ASTURIAN ROSE.—*See* PELLAGRA.

ASYSTOLE (ἀ, neg. ; and *συστολή*, a contraction). *SYNON.* : Fr. *Asystolie* ; Ger. *Mangelnde Zusammenziehung*.—The most advanced stage of progressive failure of the heart, in which the ventricular walls have become so feeble that the systole is incomplete and highly irregular, and the cavities are dilated from over-distension with undischarged blood. *See* HEART, Dilatation of.

ATAVISM (*atavus*, a grandfather).—The inheritance of a disease or constitutional peculiarity from a generation antecedent to that immediately preceding. *See* GOUT.

ATAXIA } (ἀ, priv. ; and *τάξις*, order).—Terms
ATAXIC } which originally meant any irregularity or disorder, but are now specially applied to irregularity of associated or co-ordinated muscular movements. Ataxia is frequently used as synonymous with the disease known as *locomotor ataxy*. *See* also CO-ORDINATION ; EQUILIBRIUM ; and FRIEDREICH'S DISEASE.

ATAXIC PARAPLEGIA.—*See* COMBINED DEGENERATION OF THE SPINAL CORD.

ATELECTASIS (ἀτελής, imperfect ; and *ἐκτασις*, expansion).—Absence or imperfection of the expansion of the pulmonary alveoli which normally takes place at birth, the lungs thus remaining more or less in their fetal condition. *See* LUNGS, Collapse of.

ATHEROMA.—*See* ARTERIES, Diseases of.

ATHETOSIS (ἄθετος, without fixed position).—*DEFINITION.*—A name given to a condition in which the hand and foot are in continual slow, irregular movement, and cannot be retained by the will in any given position.

DESCRIPTION.—The special character of the movements in athetosis is that they are slow and deliberate. They usually affect the arm and leg on one side only. Voluntary power is considerable, but is interfered with by the slow spasm. The fingers are irregularly flexed and extended : at one moment they spread wide apart, the thumb being outstretched ; thereafter, first one, then another, is bent into the palm, and again extended, the movements being extremely varied. They can be arrested for a moment in certain positions by the will, but are then renewed with increased force. The foot is usually inverted, the toes being flexed or extended, but in less constant movement. The spasm may cause pain. The muscles sometimes become hypertrophied. The movements in most cases cease during sleep, in some they do not. Sensation is often but not always impaired.

The onset of this condition is generally after an attack of hemiplegia, usually slight, and when it has been thought to be primary it has probably been the sequel to an attack of paralysis so trifling as to escape definite notice. Sometimes it has been preceded by sudden slight hemianæsthesia. Most patients who have presented the typical form have been in middle life.

Athetosis differs little from the spastic movement so common after hemiplegia in children. The slowness of the movements is its chief distinction, with the slighter degree of weakness and the fact that the movements are less related to voluntary movement. These distinctions are not absolute. The disorder of movement after hemiplegia may be identical in character with athetosis, and both are essentially the same in general relations. In what is termed 'athetosis' the cerebral lesion is so placed as to cause in most cases no distinct hemiplegia ; but its occurrence is indicated by the sudden symptoms which precede the slow movement. Typical athetosis may succeed hemiplegia.

PATHOLOGY.—It is probable that the seat of the lesion in athetosis is generally the optic thalamus or its neighbourhood. The sudden onset of the disease and the slight affection of sensation are in favour of this explanation of cases in which there is no distinct hemiplegia. Charcot believed that all post-hemiplegic chorea-like movements depend on the implication of fibres outside the optic thalamus. In a case of simple ataxy after hemiplegia—an analogous condition—the writer has found a cicatricial sclerosis extending across the optic thalamus, and probably left by a patch of softening. The symptoms, perhaps, may be produced in various ways, since the regulation of the motor processes in the cortex is complex. One cause may be a state of disordered action of the motor cells of the cortex, due to a prevention of the upward influence from the cerebellum. The great frequency of such 'mobile spasm' (as it may conveniently be termed) after infantile hemiplegia, when the lesion involves the white substance as well as the central ganglia, and even the motor cortex, suggests that this form may be due to disordered action of imperfectly controlled structures capable of greater recovery of function than in adult life.

PROGNOSIS.—This is unfavourable ; but slight cases may improve and more use of the hand be regained by practice.

TREATMENT.—Nervine tonics may do some good. The continuous current has been said to lessen the spasm, but, as a rule, it fails. The positive pole may be placed on the spine or brachial plexus, the negative on the muscles involved. The sedulous cultivation of the power of ordered movement by regulated gymnastics for the hand probably does more than any other measure. Upward massage sometimes seems to be of slight service. But the condition is one very little amenable to treatment.

W. R. GOWERS.

ATONY } (ἀ, priv. ; and *τόνος*, tone). Terms
ATONIC } implying want of tone, power, or vigour of particular organs, especially of those which are contractile. *See* TONE, Want of.

ATRESIA (ἀ, priv. ; and *τίρημι*, I pierce).—Absence of a natural opening or passage, whether congenital or caused by disease.

ATROPHY, GENERAL.—SYNON.: Marasmus.

DEFINITION.—Atrophy means, etymologically, simply want of nourishment (*ἀ, priv.*; and *τροφή, nourishment*), but the term is commonly applied to the condition resulting from this—namely, wasting. *General atrophy* is used to denote wasting in which the whole body participates. All acute diseases are accompanied by emaciation. The use of the word 'atrophy' is, however, confined, as a rule, to cases where the interference with nutrition has been gradual, and the loss of flesh consequently slow.

ÆTIOLOGY.—Atrophy is common enough at all periods of life. In infants and children it is due, in the majority of cases, to chronic functional derangements which interfere with the digestion and elaboration of food. Less frequently it is a consequence of organic disease. In adults general atrophy seldom results from any other cause than organic disease. In old age atrophy is a common consequence of the degenerations of tissue which accompany the decline of life. The interference with nutrition may, however, be aggravated by the presence of disease.

In *infants under twelve months old* there are four principal causes to which persistent wasting can usually be referred—namely, unsuitable food; chronic vomiting (gastric catarrh); chronic diarrhoea (intestinal catarrh); and constitutional diseases, such as inherited syphilis or tuberculosis. Bad feeding, by setting up a chronic catarrhal condition of the stomach and bowels, is a frequent cause of both vomiting and diarrhoea, but it may produce atrophy without either of these symptoms. When an infant is fed, for instance, with large quantities of farinaceous matter—a form of food which is alike indigestible and innutritious—a very small part only can enter as nutriment into the system. The remainder passes down the alimentary canal, and is ejected at rare intervals in an offensive putty-like mass, or in hard roundish lumps. The child, therefore, although overloaded with food, is really under-nourished, and loses flesh as long as such a diet is persisted in. If, as often happens, diarrhoea or vomiting be set up by the irritation to which the digestive organs are subjected, wasting is more rapid and the danger of the case is increased. Wasting, indeed, will be found in every case where the food selected is unfitted for the child, and thus it is not infrequently seen in infants who are fed upon milk and water alone. The casein of cow's milk is difficult of digestion by many infants on account of its tendency to coagulate into a large firm clot like a lump of cheese. In this respect it differs from the curd of human milk, which forms light small flocculent coagula, and is digested without difficulty. Special preparation is therefore generally required to render cow's milk a suitable diet for a young child.

It is not only, however, unsuitable food which is a cause of atrophy in infants. Catarrh of the stomach and bowels may be present, although the feeding is in all respects satisfactory. Infants are excessively sensitive to chills, and catarrh of their delicate digestive organs is easily excited. Now, catarrh of a mucous membrane is always accompanied by an increased flow of mucus, and this alkaline secretion soon begins to swarm with bacteria which set up decomposition in the food taken. Gastric disturbance from this cause may be seen in new-born infants, who thus are rendered for the time incapable of digesting even their mother's milk. In such cases the fault is usually attributed to the milk, which is said to be unsuited to the

child; and the mother is compelled, much against her will, to wean her baby and feed it in a different way. So long as the derangement continues, however, no food appears to agree, and the child often after a time dies exhausted.

Between the ages of *one and three years* atrophy is commonly associated with rickets. In these cases the wasting is noted chiefly about the chest and limbs, for the belly is large and swollen from flatulent accumulation. At this age children are still liable to waste from catarrh of the stomach and bowels; indeed, rickets is itself often complicated by such derangements. Sarcoma of the internal organs is also sometimes found at this time of life, and is attended with extreme emaciation.

After the fifth or sixth year chronic pulmonary tuberculosis begins to appear. Cases of heart-disease as the result of acute rheumatism are also more frequently seen. Diabetes mellitus, too, is sometimes met with. All these diseases may produce much interference with nutrition.

From the time that the child begins to take other food than that furnished by his mother's breast, he is liable to worms in the alimentary canal. The presence of worms is frequently accompanied by loss of flesh, not, perhaps, so much on account of the parasites themselves, as on account of the derangement of the digestive organs which is associated with them. Emaciation due to this cause may sometimes be extreme.

In the *adult* marked atrophy is almost invariably a sign of serious organic disease. All chronic ailments are not accompanied by marked wasting. Purely local diseases lead to little loss of flesh unless they affect some part of the digestive apparatus, or of the glandular system which is concerned in the elaboration of nutritive material; or otherwise directly influence the processes of nutrition. Thus, emaciation quickly results from gastric ulcer or chronic dysentery, but chronic tuberculosis may produce little diminution in weight so long as the disease remains a limited local tuberculosis, and so long as there is no pyrexia, diarrhoea, or profuse expectoration. The most marked atrophy is produced by general tuberculosis, cancer, and the infective diseases such as syphilis; by those which set up a persistent drain upon the system, such as severe albuminuria, chronic hemorrhages, and long-continued suppurations; or by those which directly impede the passage of nutritive material into the blood; and in the latter class of diseases, influences which act directly upon the thoracic duct, such as obstruction to its passage from pressure by aneurysm or other tumour, must not be overlooked. There is a form of atrophy sometimes seen in hysterical females, depending upon disordered innervation, in which the most extreme emaciation may be reached. Such cases are marked by a dislike to food which may amount to absolute loathing. See NEURASTHENIA.

ANATOMICAL CHARACTERS.—The most marked post-mortem appearance in this condition is diminution or loss of fat, especially of the subcutaneous adipose tissue; and this is accompanied by wasting of the tissues and organs generally. The histological elements are reduced in size without undergoing, as a rule, actual numerical diminution. With the atrophy is often associated a certain amount of fatty degeneration.

SYMPTOMS.—The symptoms of general atrophy are loss of flesh, loss of colour, and loss of strength,

combined with other special phenomena arising from the particular disorder to which the impairment of nutrition is due.

TREATMENT.—The treatment of general atrophy consists in removing, if possible, the impediment to efficient nutrition. In the case of a child the diet must be selected with care. Excess of farinaceous food is to be avoided, and cow's milk must be sterilised and if necessary diluted with barley water. Warm woollen clothing should be insisted upon, and special attention should be paid to the warmth of the feet. Any gastric or intestinal derangement must be at once remedied, plenty of fresh air should be obtained, and perfect cleanliness strictly enjoined. In an adult the disease which is the cause of the malnutrition must be sought for and submitted to treatment. Efforts should be made, on the one hand, to arrest any drain upon the system; and, on the other hand, by a judicious arrangement of the dietary and by attention to the eliminatory organs, to remove all obstacles to nourishment. Even in cases of organic and incurable disease much benefit may often be derived from due observance of physiological laws.

EUSTACE SMITH.

ATROPHY, LOCAL.—This condition signifies atrophy of a *part* of the body which may be produced by various causes.

Physiological Atrophies.—These form a distinct class, where atrophy of a part of the body takes place in the ordinary course of development. Such are the wasting of the thymus gland in early life, and of the mamme and sexual organs after a certain age. Most commonly the atrophy is here closely connected either with the involution or perhaps the development of some correlated organ; but it is not possible to say what the nature of this connection is, whether one of nutrition or innervation.

Acquired Atrophies.—The conditions thus distinguished possess most interest for the practical physician. Wasting of any part of the body during life, when not physiological, usually depends either upon some interference with the blood-supply, or some disturbance of innervation; but to these must be added, in the case of organs which have an active and continuous function, disuse or overstimulation. Deficient blood-supply, which causes atrophy, may be produced by the obstruction of a nutrient artery, especially if it be gradual, since sudden blocking will produce more complicated phenomena. Constant pressure is a cause of atrophy, because it interferes both with the blood-supply and with the vital actions of the tissue-elements. Intermittent pressure, on the other hand, by causing hyperæmia, is more likely to lead to hypertrophy. Moreover, inadequate renewal of blood—that is, filling of the vessels, even to excess, with venous blood—or venous engorgement, though at first it may cause enlargement, mostly leads to atrophy in the end; as is seen in the intralobular zones of the liver in cases of disease of the heart obstructing the circulation. Many forms of atrophy in old age are clearly dependent upon senile obstruction of the arteries, for example that of the skin, spleen, and kidneys. The instances of atrophy from disturbed innervation are less easy to discriminate, except where there is actual paralysis. In diseases where the nutritive centre is destroyed—progressive muscular atrophy and infantile spinal paralysis—loss of power in the muscles is accompanied by wasting, far more rapid than that which results from disuse

alone. Division of the nerve of a limb produces rapid wasting of the muscles no longer used, and this is accompanied in the end by some diminution in the size of the bones and accessory parts. Local atrophy of the skin is sometimes seen in regions limited by the distribution of a nerve, especially some branch of the fifth; and more extensive atrophy of one side of the face or head, equally marked out by nervous distribution, and resembling some cases of congenital atrophy, has also, though rarely, been observed. In such cases the writer has found anaesthesia of parts corresponding to branches of the fifth nerve, but absence of muscular paralysis, such as would be due to affection of the seventh nerve.

Disuse produces atrophy only in organs whose functions are active and constant, such as nerves and muscle. Nervous tissue wastes constantly, and sometimes rapidly, when impulses cease to traverse it. This is seen not only in the nerves of paralysed limbs, but even in the nerve-centres where any interruption of the nervous channels, either above in the cerebrum, or below in the nerve trunks, is followed by degeneration, ending in atrophy, of the whole nervous tract leading from the cerebral cortex to the peripheral termination—so-called *secondary degeneration* of the cord. In muscular tissue the wasting is almost as constant, but hysterical paralyses make an exception, the helpless limbs preserving their nutrition in a surprising manner. In organs whose functions are intermittent or periodic, disuse does not appear necessarily to produce atrophy, as is seen in the testicles, ovaries, and mammae.

That excessive stimulation or overwork may produce atrophy is seen in degenerative diseases of the nerve-centres arising from undue mental activity; and of the sexual organs from excessive indulgence. Overwork of muscles very rarely produces atrophy; but the writer has seen instances where special muscles were exposed to strain while the general nutrition was low. Atrophy of muscles is said to occur in soldiers when badly fed, after long exhausting marches.

Unexplained Atrophies.—Cases of local atrophy occur of which it is impossible to give any satisfactory explanation. Such are the conditions known as linear atrophy of the skin; some remarkable cases of atrophy of bone, especially of the skull (*fragilitas ossium*), and of some parts of the cerebrum. Atrophy of the thyroid gland appears to be certainly the cause of the disease called myxoedema, but the cause of the original atrophy is unknown.

It is possible that deficiency of special kinds of food may lead to atrophy of special organs—thus deficiency of lime may make the bones soft, and deficiency of iron arrest the development of blood-corpuscles; but even these familiar instances must be accepted with a little reserve. In the same way it is still doubtful whether any special drugs, such as iodine, can produce atrophy of special glands.

PATHOLOGY.—Wasting may occur simply, or as a consequence of change of substance, or from the intrusion of some new material; in other words, there may be *simple* atrophy, atrophy from *degeneration*, or atrophy by *substitution*. The first is probably rare; generally some change of substance occurs. The most frequent degenerative process is fatty degeneration; the albuminous substance being replaced by fatty matter, which, if afterwards absorbed, leaves a void. Organs thus

affected may be apparently enlarged, though the original substance is wasted. Atrophy from substitution is seen when the connective tissue of an organ, for instance, increases, compressing and destroying the other tissue-elements; and these not being renewed when the newly formed connective tissue contracts, the whole organ is diminished in bulk. This is seen in all the changes called cirrhosis or fibroid degeneration, as in cirrhosis of the liver and kidneys. *See FIBROSIS.*

TREATMENT.—No general rules can be laid down for treating all cases of local atrophy. Where the blood-supply is deficient, we have rarely any means of supplementing it; where innervation is at fault, it is seldom under our control. In general, harm rather than good results from any attempt to attract blood by artificial irritation. In the case, however, of atrophy from disuse of the nervo-muscular system, a line of treatment, and more especially of prophylaxis, is very early indicated; this is, to keep the muscles in exercise by artificial means, particularly by electricity, or by the processes of friction and kneading combined with passive movement (*see* MASSAGE). In this way so much of the atrophy as is due simply to disuse may be checked for the future, and even the former loss repaired. We shall, moreover, never do harm by attempting to supply some special elements of food which appear to be deficient, as iron for the blood and phosphorus for the bones or nervous system.

J. F. PAYNE.

AUDITORY MEMORY.—*See* APHASIA.

AUDITORY NERVE, Diseases of.—*See* EAR, Diseases of; and HEARING, Disorders of.

AURA (*αἶρα*, a breeze).—A peculiar sensation, subjective in origin, immediately preceding an epileptic or hysterical convulsion, and named respectively *aura epileptica* and *aura hysterica*. The word was adopted at a time when the arteries were believed to contain air because the sensation described was that of the passage of cold air from the trunk or extremities to the head; but it has been extended so as to include any phenomenon, whether sensory or motor, that ushers in a fit of epilepsy or of hysteria.

AURAL DISEASES.—*See* EAR, Diseases of.

AUSCULTATION (*ausculto*, I listen).—A method of physical examination, which consists in listening over various parts of the body, either by the direct application of the ear (*immediate auscultation*), or by the aid of special instruments (*mediate auscultation*), for the purpose of studying certain sounds produced in health and disease. *See* PHYSICAL EXAMINATION.

AUSCULTATORY PERCUSSION.—A method of physical examination, in which the sounds elicited by percussion are studied by means of auscultation. *See* PHYSICAL EXAMINATION.

AUSTRALASIA.—The portion of Polynesia lying between 10° and 50° S. latitude, and 110° E. and 170° W. longitude, which may be said to include Australia, Tasmania, New Zealand, the Fiji Islands, the New Hebrides, and some less important islands.

Australia.—The climate of the vast continent of Australia, which is partly temperate and partly

tropical, depends, first, on its latitude, and, secondly, on its conformation, the mountain ranges being distributed along the coast-lines, especially on the eastern shores. In the interior, which is comparatively flat, and believed to be for the most part a sandy desert, there is great heat and little rain. The hot winds from the interior are often sufficient, in the summer, to raise the thermometer to 127° F., and on the amount of protection from these enjoyed by the various towns depends their climate. There are also sea-winds from the N. and N.E. The southerly winds, prevailing chiefly from November to February, blow from the Antarctic Circle, and are cold winds of great velocity, ending in heavy thunderstorms. In the tropical region the rainfall is from November to April; and in the temperate, which lies to the east and south, it prevails only in the winter season.

The following are among the principal towns or centres to which invalids proceed:—

Adelaide, the capital of South Australia, lat. 35° S., long. 135½° E. This place suffers from great heat and drought. The mean temperature is 65°, the maximum 115°, and the minimum 34°; the range being 81°, and the mean daily range 20°. The humidity is 60 per cent., and the rainfall 21 inches, but varies greatly. The soil is sandy.

Brisbane, the chief town of Queensland, lat. 27½° S., long. 153° E. The climate is almost tropical. The mean temperature is 70°, the maximum is 108°, the minimum 34°; the range 74°, with a mean daily range of 21°. The rainfall is 51 inches, and the mean humidity 76 per cent. Queensland is for the most part elevated; and the climate of the Darling Downs, on an average 2,000 feet above sea level, is considered very fine. The townships at Toowoomba and Warwick in this region may be recommended.

Melbourne, the capital of Victoria, lat. 38° S., long. 145° E. It has the reputation of being a healthy and agreeable residence; the climate being dry and temperate, and far cooler in summer than that of Sydney. Mean temperature 57°, maximum 111°, minimum 27°, showing a range of 84°; daily range 18°. Mean humidity 72 per cent. Rainfall, 26 inches.

Perth, in Western Australia, very healthy, but as yet little suited to the requirements of invalids. The temperature is 63° (mean), and the rainfall 30 inches in 110 days.

Sydney, the capital of New South Wales, lat. 34° S., and long. 151° E. The climate of New South Wales is clear and dry, the temperature depending more on the altitude than on the latitude. The plains in the interior, swept by hot winds, are very dry, while the coast-districts have abundant rain. Mean temperature 62·5°, maximum 107°, minimum 36°; range 71°; mean daily range 14°. Humidity 72 per cent., and rainfall 50 inches. Paramatta, on Port Jackson, is drier and cooler than Sydney (Lindsay); and the Illawara district, including the stations of Eden and Twofold Bay, is suitable for invalids; but the finest climate in Australia for pulmonary cases is to be found in the Riverina, a district lying between Queensland, the Blue Mountains, and the central desert, consisting of rolling prairie and undulating downs, with a rainfall ranging from 5 to 24 inches, the average being 14 inches, and a clear bright atmosphere, most exhilarating in its effect on invalids, who at the

settlements of Deniliquin, Bathurst, Menindee, and the various sheep-farms, pursue an open-air life by day, and often by night, with great advantage. The district of Bourke, 500 miles from Sydney, is also well spoken of.

Tasmania.—Tasmania lies 150 miles south of Australia, between lat. $40^{\circ} 40'$ and $43^{\circ} 38'$, and is mountainous, with a deeply indented coast-line. The climate is more temperate and equable than that of the south coast of Australia. In winter the cold is sufficient to produce thin ice in the low lands, and snow-showers in the higher ranges. The mean temperature of *Hobart Town* on the S.E. coast is 54° , the summer mean being 62° and the winter 47° . The rainfall varies greatly, from 100 inches at Macquarie Harbour on the W. coast to 24 inches at Hobart Town, distributed over 145 days. The prevalent winds are from the N.E. and S.W. The climate is favourable to infant life, and the country is regarded as a sanatorium for invalids.

New Zealand.—New Zealand lies between $34^{\circ} 50'$ and $47^{\circ} 50'$ S. lat., and consists of a North and a South besides smaller Islands. The North Island is for the most part volcanic, and abounds in hot springs, which are extensively used, and active craters, which impart an important influence to its climate. The South Island contains a lofty range of snow-clad mountains, whose lower slopes form on the eastern shore a series of terraces known as the Canterbury Plains, and other fertile regions.

The climate is mild and bracing, but decidedly of a windy character, and not suited for all invalids: at Auckland in 1876 no calm day was recorded, the prevalent winds being W.S.W. The mean temperature of the North Island is 58° , of the South 54° . The maximum varies from 87° , at Christ Church, to 75° , at Hokitika, and the minimum from 25° to 34° in the South Island. Cold is as a rule unknown in the North Island, while in the South there are a few snowy days each year on the coast. The rainfall varies from 32 inches in 135 days at Christ Church, to 131 inches in 186 days at Hokitika.

Fiji Islands.—The Fiji Islands, partly of volcanic and partly of coralline origin, have a tropical climate, moderated by the trade-winds, so that the mean temperature does not exceed 80° , the minimum being given as 65° . The rainfall is chiefly from October to April—the hot season—and varies from 124 to 215 inches in 170 days. See CLIMATE, Treatment of Disease by.

C. THEODORE WILLIAMS.

AUTO-INTOXICATION (αὐτός, self; τοξικόν, poison).—DEFINITION.—By auto-intoxication is meant a process of poisoning brought about by some substance or substances produced by the body of the poisoned animal.

DESCRIPTION.—Certain diseases which are not strictly included in this definition are sometimes quoted as examples of auto-intoxication.

(1) In the first place, the specific infectious fevers must be mentioned. The symptoms of these diseases are produced by products of the specific microbe, and not by substances formed in the course of the patient's metabolism. (2) Secondly, the so-called gastric and intestinal auto-intoxications are, for an analogous reason, not to be regarded as instances of this kind of poisoning, for the condition of the urine and fæces in these cases shows that there

is an increase of bacterial putrefaction in the alimentary canal. When this putrefaction is lessened, these symptoms disappear; and we are therefore justified in concluding that these are cases of intoxication by substances manufactured in the alimentary canal by micro-organisms. The fact that these substances are produced to a lesser extent in health shows that these morbid conditions may be merely exaggerations of the ordinary events of healthy life, but is not a valid reason for including these cases among the auto-intoxications.

Instances of auto-intoxication will be here considered (1) experimentally, and (2) clinically.

1. Experimental.—The most striking instance of auto-intoxication among higher animals is the series of events resulting when the animal breathes in a closed space, although in the final asphyxia other factors probably play a more important part.

Among bacterial forms of life auto-intoxication is a common occurrence under artificial conditions of growth. It is produced, not by deficient excretion of a poison from the cell, but by the accumulation of a poisonous substance in the culture-medium. The causes of this auto-intoxication are known in some cases. For instance, *Bacillus pyocyaneus* produces an enzyme-like body, which can be precipitated and purified by alcohol, and which destroys fresh cultures of *Bacillus pyocyaneus*, as well as those of other micro-organisms.

One argument for the occurrence of auto-intoxication in man and higher mammals is based on experimental evidence. Various excretions, secretions, fluids, and solids of one healthy animal are toxic for another animal of a different species. It is possible, therefore, that these products may be toxic also for the animal by which they are formed. Failure of excretion, or of destruction, of these poisons might lead to auto-intoxication. Generally speaking, substances poisonous for one species of mammal are also poisonous for another species: various species, however, differ largely in susceptibility; moreover, in the case of certain toxins which destroy the red corpuscles, there are many exceptions to this generalisation. Only in a few cases has an animal product been shown to be toxic for the organism which forms it. These cases are mentioned in the following account of the toxicity of various organic fluids and solids.

Urine.—The urine of many animals (especially of herbivora) is toxic for other animals. The symptoms produced by intravenous injection of human urine into a rabbit are: myosis, acceleration of respiration, frequency of micturition, lowering of temperature, and finally coma, with or without convulsions. French observers give the average minimal lethal dose as 40 c.c. per kilogramme of animal. The toxicity of human urine varies under different circumstances in health. It is diminished in old age and by fasting, and increased by muscular exercise. The toxicity is said to be least when sleep begins, and much greater during waking hours. Qualitative differences between the urine of the night and day have been recorded. The urine contains a large number of substances which are able to produce morbid symptoms and ultimately death. In view of recent research, it is probable that much of the toxicity of the urine is due to the salts of potassium which it contains. After dialysis, however, the urine is stated to be still toxic. Further, a certain connection has been traced in some cases between the toxicity of the urine and the

amount of conjugated sulpho-acids present. The latter are evidence of increased bacterial putrefaction in the alimentary canal.

On comparing the figures given by various authors as representing the average toxicity of normal urine, they are found to differ very widely one from another. Bearing this in mind, the statements that have been made as to the toxicity of the urine in various pathological conditions must be received with great caution. These statements are for the most part unconfirmed.

Blood.—The serum of one species of animal is, generally speaking, toxic for another species—apart from its hemolytic, coagulative, or agglutinating powers. Albuminuria has been recorded as the result of the injection of serum from another animal of the same species but of different sex. Doubtless some of the effects of the serum are due to changes in the plasma brought about by clotting; among these is the rise of temperature. Recently it has been found that the blood of the cat after clotting becomes toxic for the same animal; and Richet has recorded a choreiform condition in dogs brought about by repeated injection of dog's blood.

Among other toxic substances should be mentioned *bile*, *saliva*, *gastric juice*, and extracts of *supra-renal capsules*, *thyroid gland*, and *muscles*. Sterile sweat is said to be non-toxic (Brieger).

The kidneys excrete many poisonous substances from the body, but there is another organ—the *liver*—whose function as a destroyer of poisons can be regarded as well established. The liver has the power of destroying certain poisons (e.g. some alkaloids) when introduced into the blood-stream. Doubtless the liver acts similarly in health; and we might therefore expect that in diseases of the liver auto-intoxication would occur from impairment of this function. Other organs have been supposed to act as destroyers of poisons, notably the thyroid gland; they will be mentioned later.

2. Clinical.—The occurrence of auto-intoxication has been thought probable in the following conditions:

1. Breathing in a closed space.—The mere excess of carbon dioxide in the air does not account for the resulting symptoms; for air containing a large quantity of this gas may not give rise to them, although air that has been 'vitiated' by breathing does, and yet contains less carbon dioxide than in the first case. It is not quite clear, moreover, to what extent the symptoms are due to a substance excreted by the lungs, or by the skin. It is of course possible that the bacteria of the skin may produce a toxic substance.

2. Diseases of the kidneys.—In *uræmia* and *puerperal eclampsia* some of the symptoms at least are probably due to auto-intoxication. With regard to uræmia, it may be said that no substance known to occur in the urine is capable of producing all the symptoms of this condition, though many (urea,

salts of potash and ammonia, carbamic acid, &c.) have been suggested as causes.

3. Diseases of the Liver.—Among these may be mentioned *acute yellow atrophy*, and cases of severe *jaundice* from any cause. It is stated that bile-salts cause diminished frequency of the heart-beats—a common symptom in jaundice.

4. Diseases of the thyroid gland.—*Myxædema*, *cachexia strumipriva*, *exophthalmic goitre*.

5. Diabetes.—The causes of *diabetic coma* are unknown, though acetone and β -amido-butyric acid have been suggested.

6. Addison's disease.—Many physiological experiments can be explained by the hypothesis that the supra-renal capsules render certain poisonous substances innocuous. It is therefore conceivable that the abolition of the function of these glands would lead to an auto-intoxication.

7. Burns.—Some of the symptoms of severe burns are due to the circulation in the blood of some poisonous substance, produced at the seat of the injury.

8. Gout.—The statement that gout is an auto-intoxication does not alter the degree of obscurity in which the pathology of this disease is shrouded. The presence of sodium urate in the various joint structures is doubtless a cause of the local symptoms.

In the present state of knowledge, auto-intoxication should be regarded as a suggestive conception founded upon analogies. Although its occurrence is probable in certain diseases, the experimental evidence is insufficient to allow of very definite statements as to the conditions in which auto-intoxication plays a part, and still less as to the substances producing it.

WALTER MYERS.

AUTOPHONIA (*αὐτός*, himself; and *φωνή*, the voice).—A physical sign obtained by studying the modifications of the resonance of the observer's own voice during auscultation. See PHYSICAL EXAMINATION.

AUTOPSY.—See NECROPSY.

AX-LES-THERMES, in the South of France. — Thermal waters. See MINERAL WATERS.

AXON (*ἄξων*, an axle).—The largest and longest of all the processes proceeding from a nerve-cell is called the axon. The axon is the channel by which impulses are conveyed from the cell.

AZORES; St. Michael.—Warm, very moist, equable climate. Mean winter temperature 58° F. Prevailing winds N. and E. See CLIMATE, Treatment of Disease by.

AZOTURIA.—A condition of the urine in which there exists an absolute and relative excess of urea, without accompanying pyrexia. See URINE, Morbid Conditions of.

B

BABINSKI'S SIGN.—This term is applied to a modification of the superficial plantar reflex, obtained by stroking or tickling the sole of the foot. In normal persons the reflex starts with flexion of the toes, followed by dorsiflexion of the ankle and flexion of the knee and hip (*flexor response*). In patients who are the subject of degenerative changes in the lateral columns of the spinal cord (pyramidal tracts) the reflex occurs more slowly and starts with extension of the great toe, followed by the other toes, with increase of the curvature of the plantar arch (*extensor response*). This phenomenon was first described by Babinski: it is of value in differentiating cases of organic disease of the lateral columns from so-called 'functional' conditions.—See SPINAL CORD, Diseases of.

W. CECIL BOSANQUET.

BACILLI (*bacillum*, a little rod or staff).—SYNON.: Fr. *Bacilles*; Ger. *Bacillen*. See BACTERIA.

BACILLI, various.—See under Diseases produced by them.

BACILLUS COLI COMMUNIS.—SYNON.: *Bacterium coli commune*; Colon-bacillus.

The *B. coli communis*, a constant inhabitant of the intestinal canal of man and several other mammals, is a short rod with rounded ends, sometimes ovoid in shape, 2 or 3 μ in length by 0.4 to 0.6 μ in breadth. 'Thread' forms, 6 to 10 μ or more in length, are of common occurrence in artificial cultures. The bacillus is feebly motile—its activity varying greatly in different specimens: it possesses from 2 to 10 lateral flagella. The organism stains well with all the aniline dyes, but is decolorised by Gram's method.

It is a facultative anaërobie, growing readily upon artificial nutrient media (even those containing as much as 0.15 per cent. of phenol) at temperatures ranging from 20° to 42° C. Spore-formation does not occur. Its thermal death-point is 60° C., the time of exposure being ten minutes.

CULTURAL CHARACTERS.—*Gelatine Plate-cultures.*—The superficial colonies, at first round and almost transparent, later become opalescent, spread rapidly and show irregular crenated margins, with granular surface marked by ridges and furrows, and heaped-up centres. The deep colonies are spherical, of a pale buff colour, and granular in appearance. The gelatine is not liquefied.

Gelatine Streak-culture shows a white shining flat growth, with irregular margins, spreading out laterally from the needle-track. In old cultures the growth becomes iridescent, and a hazy 'ground glass' appearance of the adjacent gelatine is noted.

Gelatine Slab-culture.—White spherical colonies develop in the entire extent of the needle-puncture, afterwards becoming confluent. Growth also spreads over the surface of the gelatine from the point of entrance. One or more gas-bubbles may appear in the depths of the medium.

Sugar-gelatine Shake-culture.—Abundant formation of gas (CO₂ and H) is evidenced by the appearance of numerous bubbles of gas in the substance of the medium.

Bouillon.—A uniform turbidity is noted in this

medium after from 10 to 12 hours, a fair amount of deposit being apparent at the bottom of the tube at the end of two days. A peculiar faint odour is given off from bouillon-cultures, and the presence of indol can be demonstrated in from 24 to 72 hours.

Agar Streak-culture shows a luxuriant growth in the form of a raised thick moist shining greyish-white sticky layer.

Streak-culture on Inspissated Blood-serum.—Growth as on agar. The medium is not liquefied.

Potato-culture.—A thick slimy layer of a buff or brownish-yellow colour develops upon the surface of the potato. The substance of the potato may or may not be discoloured.

Milk culture.—The milk is curdled in from 24 to 48 hours as a result of the action of the lactic acid produced by the growth of the bacillus.

PATHOGENESIS.—The *B. coli communis* is pathogenic for the ordinary laboratory animals, i.e. rabbit, guinea-pig, mouse, although variations in virulence among different specimens are quite common. Those strains which are but slightly pathogenic can usually be exalted in virulence by means of intraperitoneal or intrapleural passages. Virulent cultures, when introduced into serous cavities, frequently cause a true septicæmia, and the colon-bacillus can then be recovered *post mortem* from the heart-blood. When less virulent cultivations are injected, or the subcutaneous method of inoculation is employed, death ensues either from toxæmia or from pyæmia, small masses of the bacilli being found in the spleen and other organs, giving rise to localised collections of pus; in other cases again, a local abscess only is produced—the animal ultimately recovering.

In man the colon-bacillus has its normal habitat in the intestinal canal; in any other situation its presence must be regarded as abnormal, and pus-formation be expected. It has been shown by Malvoz that, given an injury to the bowel-wall, the colon-bacillus is capable of penetrating it at that spot and so making its way into the peritoneal cavity, even when such injury is insufficient to cause perforation, thus explaining the common occurrence of peritonitis as a sequel to strangulated hernia or appendicitis. Sanarelli showed that the colon-bacillus isolated from a patient suffering from typhoid fever possesses a higher degree of virulence than one obtained from a normal individual; and it has been further shown that a greater proportion of the pyogenic processes complicating the later stages of enteric fever are due to the colon-bacillus than to the typhoid-bacillus.

Many urinary infections such as pyelitis, ureteritis, and cystitis, notably that following operations upon the rectum, are also due to the presence of the colon-bacillus in an abnormal situation. See APPENDIX VERMIFORMIS, Inflammation of.

JOHN EYRE.

BACTERIA (*βακτήριον*, a rod).—SYNON.: Fr. *Bactéries*; Ger. *Bakterien*.—INTRODUCTORY.—Bacteriology is concerned with one of the lowest orders of living things, for which the name *bacteria* has been adopted. In its original application the term bacteria was restricted to such of these organisms as were of an elongated rod-like

shape, but its connotation has been extended to include all members of the same group irrespective of form, and it has thus come to have a generic significance. In fact it is practically synonymous with 'micro-organism,' which in its strict sense might be applied to any living body of microscopic dimensions. In medical parlance, however, both terms are limited to those minute organised structures which may be associated causally or otherwise with disease, and indeed are generally understood to refer only to such as are presumably of a vegetable nature. The terms 'microbe,' 'microzyme,' 'germ,' &c., may be regarded as equivalent.

It is well to indicate at the outset that the scope of the present article is limited. Any systematic description of individual bacteria is excluded, each being dealt with under the heading of the morbid condition with which it is specially associated. The important subjects of toxins, antitoxins, and immunity are also separately considered. The aim has been to present in a succinct form some of the more important facts as to the morphology and life-history of bacteria and the methods of investigation employed.

Moreover, reference will especially be made to those bacteria which are concerned in the production of disease in man. It is, however, noteworthy that myriads of bacteria exist in the air, in water, and in the soil, and that only a small proportion have any pathogenic effect. The vast majority display other activities, many of which have a far-reaching beneficial result. For example, bacteria are the chief agents in the decomposition of effete animal matter, in the purification of sewage, in many processes of fermentation of great industrial importance, and in the fixation of free nitrogen and oxidation of ammonia and nitrites to form compounds adapted for the nutrition of higher organisms.

NATURE OF SPECIFIC CONTAGIA: CONDITIONS OF CAUSAL RELATION. (For general considerations see INFECTION.)—The grounds on which any micro-organism can justly be regarded as the contagium or actual cause of disease may be briefly indicated. 1. It must be constantly associated with the disease, being present in the fluids or tissues of the diseased animal, and in the virus by which the disease is communicated. It may indeed be in a different form in the virus, e.g. in the form of spores, while in a more developed form when in the full activity of disease-production. We should expect that if there is a characteristic lesion, such as an eruption, or some special affection of one or more organs, the organisms should be concentrated there. 2. The organism should be capable of absolute isolation and separate cultivation outside the body; and then, being introduced in the form of a pure culture, it should produce the same disease and be capable of re-transmission to other individuals.

It is obvious that this rigorous scientific proof can be attained almost solely in the lower animals, seeing that we cannot, in the more serious diseases, thus experiment on man. And even in the lower animals we meet with numerous inherent difficulties. 1. Some micro-organisms can be cultivated outside the body only with great difficulty, others at present not at all. 2. The specific disease-producing properties may be greatly diminished, or even lost, in artificial conditions of growth. 3. A further difficulty, which forms an especial barrier to

the study of human diseases, is found in the fact of the variations of disease when communicated from one class of animal to another, and in the relative degree of susceptibility to disease of different classes, or even of species or individuals of a given class. Thus we find (a) that a virus which causes a general blood-poisoning in one class of animals will produce only a local lesion in another, (b) that none of the conditions produced in lower animals may correspond with the disease as we are familiar with it in the human subject, or again (c) that some human diseases are transmissible to animals only with difficulty, or not at all.

If, by analogy in all essential points, a disease comes into the group of contagious specific diseases, and is strictly comparable with one in which a bacterium has been proved to be the actual virus; if, further, there is constantly present in the body, and especially if in the specific lesion and in the virus, an organism having definite characters, we may provisionally regard it as the essential contagium. And still more may we do so if we find that the disease can be transmitted with the same characters to another individual by employment of fluid or tissue which contains this organism, and that it is not transmitted if the fluid or tissue employed for inoculation does not contain the organism, although derived from an animal suffering from the disease and containing the organism in other parts.

Of the diseases affecting man, anthrax and tuberculosis may be mentioned as examples of conditions, the bacterial origin of which is absolutely proved. Leprosy is one in which the final proof of inoculation of isolated cultures is yet wanting, but is the only missing link. Relapsing fever is an instance of inference from transmission of the organism and the fever to monkeys. Syphilis is an example of a disease in which there exists evidence from analogy only, although some of the organisms discovered may prove to be the virus.

GENERAL MORPHOLOGY AND BIOLOGY.—*Higher and Lower Forms.*—In the consideration of bacteria it is well to regard as a separate order, somewhat higher in the grade of vegetable life, those forms which show a higher degree of complexity and greater variation in their forms or stages of development under different conditions of life. Hence it is convenient to speak of the *higher* and the *lower* forms of bacteria, and to describe them more or less separately. Apart from minor details the higher bacteria differ in two important characters from the lower forms—in structure and in function. 1. In structure the elements which constitute the higher forms are more intimately related to each other. They form filaments which may be septate or non-septate, and which may or may not show a true branching. In every case the component parts of each filament are closely bound up with one another in a common sheath; and in the more highly developed members of the group the filaments present a uniform appearance with no trace of their individual constituents. In structure, therefore, they represent a transitional stage between the more complex mycelium of a fungus and a thread of bacilli in which each component is a separate individual. 2. While morphologically the constituents of the higher forms have become mutually more dependent, there has also been developed a greater functional differentiation or specialisation. Thus one extremity of the filament

may be concerned merely in fixation, while certain of the free extremities or hyphæ are set apart for the reproduction of the species. In the lower forms any individual may take upon itself the part of multiplying to form other individuals, but in the higher forms this power is confined to a limited number of elements.

The higher bacteria include such forms as *Beggiatoa*, *Leptothrix*, *Cladothrix*, and *Streptothrix*, but as a group they are less concerned in human disease than are the lower forms. Of this group most of those known to be pathogenic belong to the *Streptothriciæ*, and among them the member of greatest pathogenic importance is *Streptothrix actinomycetes*. See *ACTINOMYCOSIS*.

The lower bacteria are minute unicellular organisms belonging to the lowest class of chlorophyll-less algæ, and constituting the most elementary form of vegetable life. It may be noted that in some non-pathogenic bacteria chlorophyll granules have been described, but the general fact is as stated. They multiply by fission; hence the name *Schizomycetes*, but for many of them there is also a mode of propagation or a resting-stage constituted by the formation of spores. In structure they consist of a protoplasmic body having peculiar chemical and physical characters, enclosed within a cell-envelope. Many are spontaneously motile.

Form, Size, and Grouping of the Cells.—The bacterial cell may present great variety in *form*, but is for the most part symmetrical, though slight degrees of asymmetry are very common. If there is no great disparity in length between any one diameter and the others, the cell has a more or less spherical or ovoid form, and the organism is spoken of as a *coccus*. If, however, one diameter definitely exceeds in length the other two, the cell has a cylindrical or rod-like form to which the terms *bacillus* and *spirillum* have been applied—the former when the rod is straight or only slightly curved, the latter when the curvature is more marked. Even in the case of the cocci considerable diversity of form is met with. Some are approximately spherical, except when undergoing processes of division or degeneration. Others have one diameter rather longer than the other two—e.g. the *Pneumococcus*, in which also one extremity is rounded and the other so pointed that the term ‘*lanceolatus*’ has been applied to it. In others one diameter is rather shorter than the other two, so that the organism has a flattened shape and discoid outline, as in the *Gonococcus*, *Diplococcus intracellularis meningitidis*, &c. Among the bacilli there is still greater variation in form. Some are so short as to resemble oval cocci, as in Friedländer’s pneumobacilli, while others attain a relatively great length, as in anthrax. On cross-section some are exceedingly slender, while others are relatively thick. In some the extremities are rounded or even pointed, as in clostridium-forms, whereas in others they are abruptly truncated. Some present the appearance of a uniform cylinder with parallel sides; others show bulbous swellings throughout their length or at one end. The spirilla may occur, as in cholera, in the form of minute rods, each with a single curve and tapering towards the ends, or, as in the spirillum of relapsing fever, in the form of delicate spiral threads, each showing several twists or curves.

In *size* they are extremely minute. Most of the rounded forms do not exceed 1μ or $\frac{1}{25000}$ inch in diameter. The largest of the pathogenic rod-like

forms, the *Bacillus anthracis*, rarely exceeds in length the diameter of a red blood-corpuscle, and most bacilli are less than half that length. In thickness they vary from a maximum of about 2μ to a minimum of less than 0.5μ . Most of the pathogenic spirilla are very short, rarely exceeding 2μ in length, but the slender spirillum of relapsing fever may reach a length of several times the diameter of a red blood-corpuscle.

The arrangement and *grouping* of the individual cells depend partly upon the viscosity of the cell-envelope and pericellular material, partly upon the mode of fission, and partly upon the consistence of the medium in which the organism is growing. Hence, after fission, some cocci tend to remain in pairs or groups of four and eight, some form chains, others irregular bunches. Some bacilli occur chiefly in pairs, others in long filaments, and others singly. Growth in a fluid medium favours the development of characteristic grouping of bacterial cells.

The Cell-Protoplasm.—In the unstained condition bacteria appear as sharply outlined, highly refractile, almost colourless bodies. The cell-protoplasm has a marked affinity for the basic aniline dyes, and when stained it may present a uniform homogeneous appearance, but is frequently granular, showing differences in the staining-reaction in different parts. More profound changes affecting the entire cell may be observed during the processes of spore-formation and of involution or degeneration. In some bacteria, and very typically in the bacillus of bubonic plague, the protoplasm appears to be condensed at each extremity or pole, and there takes on a deeper stain than in the centre. Such organisms are said to show *polar staining*, and the deeply stained parts are sometimes spoken of as *polar granules*. In other bacteria, e.g. *B. diphtheriæ*, the cell-protoplasm shows a series of condensations throughout its length, so that each bacillus appears to be made up of a row of deeply stained granules, and many resemble a short chain of streptococci. When suitably stained these granules may take on a different colour from that of the rest of the cell-protoplasm and are known as the *metachromatic granules*. Vacuolation may be observed in the cell-protoplasm of many bacteria. The presence of a *nucleus* is disputed. The more deeply staining granules in the cell-protoplasm have been regarded as the first indication of nucleus-formation (Migula). From observations on some of the larger non-pathogenic forms, it has been inferred that the greater central part of the bacterial cell corresponds to the nucleus, and that the cell-protoplasm is represented by a peripheral layer within the envelope, so scanty as to elude observation in the majority of instances (Bütschli). It is an open question how far these appearances correspond to normal structural features, and how far they are due to degenerative changes in the bacteria or are produced by artificial means. In the fixation of films for examination an interchange may take place between the cell-protoplasm and the surrounding fluid, so that phenomena of *plasmolysis* may occur, giving rise to granulation, vacuolation, and apparent nucleation (Fischer). The presence of a protoplasmic meshwork (Bütschli) and of lymph-spaces (Migula) in the bacterial cell has also been described.

Chemistry of the Bacterial Cell.—The chemical composition of the protoplasm appears to vary in different species, and in the same species under different conditions. Nencki extracted from the

bodies of certain bacteria a peculiar albuminous substance which he termed *mycoprotein*, and from the spores of anthrax a somewhat different substance, *anthraco-protein*. Buchner also isolated certain nitrogenous bodies or proteins, which differed from those of Nencki in containing phosphorus, and other observers have described various albuminous constituents. Granules of definite chemical composition have been found in the cell-protoplasm—e.g. sulphur in *beggiatoa* and *thiothrix*, starch-granules in *B. amylobacter*, droplets of oil or fat and iron-compounds in other organisms.

Bacterial Pigments.—Not a few organisms, chiefly non-pathogenic forms, when grown in mass show distinctive colours, pink, red, yellow, orange, green, violet, black, &c. Whether the pigment belongs to the protoplasmic body or to its envelope cannot in most cases be determined, as the small size of the cells renders the colouring matter invisible when they are examined singly. In many relatively large forms the pigment appears in the cell-contents; in others it is deposited in little granules between the cells, and in others it is held in solution by the medium. Certain conditions of growth, e.g. relation to oxygen, temperature, &c., may modify or arrest the production of pigment. The chemical nature of bacterial pigments is not always the same. Some belong to the group of lipochromes—pigments analogous to those derived from animal fat and widely distributed throughout the animal and vegetable kingdom (Zopf)—and include bacteriopurpurin found in the large sulphur-bacteria. They are insoluble in water and frequently colour the growths of bacteria in nutrient media. Others are soluble in water, and are therefore not confined to the colonies, but are diffused throughout the media. They have been isolated from the fluorescent bacteria and in a dry state consist of an amorphous albuminoid substance. Other bacteria furnish colouring matter of which the chemical nature is still less known. The occurrence of chlorophyll in some forms has been noted.

The Cell-Envelope.—The protoplasm of all bacteria is enclosed in, and usually sharply defined by, a delicate membrane. In some of the higher forms a distinct sheath can be seen, but in many of the lower forms the envelope is revealed only in certain conditions or by special reagents such as iodine, tannic acid, &c. As regards its physical characters the envelope appears to consist of two layers. The inner layer is a thin, highly flexible, and elastic membrane which readily adapts itself to any movement of the bacteria. The outer layer is less defined and has in many species a peculiar glutinous or viscid consistence, so that after fission the individual elements may form characteristic groups. To the partial solution of this material is due the intercellular substance of zoöglea-masses.

In some bacteria the envelope has a tendency to become greatly swollen, forming the so-called 'capsule.' This occurs most typically during the parasitic stage of the organism, and is usually absent or only barely evident in cultures. It forms a characteristic structural feature of Fraenckel's pneumococcus, Friedländer's pneumobacillus, and other forms. It remains unstained by ordinary aniline dyes, but may be stained by special methods (*vide infra*). An important point is that capsules appear to have greater powers of resisting necrosis and degeneration than the bacteria themselves, so that in an old empyema, for example, it is often

possible to detect the persistent capsules of pneumococci, although their protoplasmic bodies have entirely disappeared.

In its chemical constitution the envelope appears in most instances to be a carbohydrate related to cellulose, or to contain also chitinous substances related to the cellulose-group in their reaction. The envelope of some (e.g. *B. xerosis*) is supposed to be largely fatty (Neisser).

Motility and Flagella.—When examined in suspension in a fluid, many bacteria are found to be actively *motile*, showing spontaneous movements of a darting, rotatory, or undulatory character. In some of the higher forms (e.g. *Beggiatoa*) independent movements are due apparently to the contractility of the cell-protoplasm: but in practically all the lower motile forms special structures termed *flagella* are known to be present; and most of the spirilla, many bacilli, and a few cocci are furnished with them. They consist of relatively long and exceedingly delicate wavy filaments, which proceed from the sides or ends of the organism. When terminal they may be single or double or manifold, and placed at one end only or at both ends of the cell; when lateral they are often very numerous. Whether they are direct prolongations of the cell-protoplasm or merely modified appendages of the envelope is an open question. In a few very large organisms the unstained flagella may be seen, but in the majority they are not revealed except by special methods of staining (*vide infra*).

Motility is not usually characteristic of an organism throughout the whole cycle of its life-history. It becomes modified by age and by sporulation, and this modification is associated with loss of the flagella. As a rule young cultures show most active motility, but in suitable conditions movement may persist and flagella be demonstrated after many days. In older cultures flagella tend to disappear and all movement to cease. The onset of sporulation in a motile organism usually coincides with shedding of most of the flagella and a loss of motility, e.g. *B. tetani*. But without loss of flagella motility may be affected by such conditions as the nature of the medium, the temperature, and the presence of agglutinins in antisera. On this depends the characteristic reaction of the bacteria to the serum in such diseases as typhoid fever, cholera, &c. The movements of bacteria in the phenomena of positive and negative chemiotaxis are not necessarily associated with the presence of flagella.

Involution-Forms.—As age advances and in certain conditions of environment all bacteria tend to undergo degenerative changes, and the intracellular vacuoles and granules above noted probably indicate the onset of such changes. But many organisms in process of degeneration undergo very remarkable transformations which are known as 'involution-forms.' Thus pneumococci and gonococci in cultures rapidly lose their definite shape and size, become swollen and globular, and show irregular staining. Many bacilli also undergo similar changes, notably those of plague and diphtheria. In the former extreme variations are possible, the small oval bacilli becoming swollen to rounded, ovoid, or pyriform bodies, and even adopting the appearance of a branching mycelium (Muir). In the latter, granularity and segmentation of the protoplasm, and a tendency to form large club-shaped bodies are prominent features. The cholera-spirillum too may undergo irregular swelling and clubbing, and

many individuals become transformed into faintly staining coccoid bodies.

Reproduction.—(a) In the higher forms certain elements are set apart for reproductive purposes, and multiplication occurs from conidia borne on special hyphæ. (b) In the lower forms reproduction takes place by direct division or fission of the cells, the segments being often of nearly equal size. Transverse fission is the rule in the simpler rod-shaped and spiral forms, and the daughter-cells elongate, so that, if the segments do not separate, they come to form long filaments. Long or short chains of streptococci are similarly produced. But in some of the rounded forms division may occur in two planes at right angles to one another, thus forming groups of four (*tetrads*), or in three dimensions forming cubical groups of eight (*sarcinae*). During the process of fission a constriction appears in the plane of approaching segmentation, and a delicate line may be seen across the cell-protoplasm cutting it in two. The constriction increases and the delicate transverse line undergoes a gelatinous swelling until two individuals appear, separated by an interval of varying width. The ultimate arrangement of the individual elements depends partly on the planes of fission, partly on the viscosity of the cell-envelope, and partly on the consistence of the medium, and can therefore be regarded only as a subordinate character, although it affords a basis for an elementary classification. The rate of multiplication varies greatly in different species and in different conditions of growth. The bacillus of tuberculosis grows relatively slowly, but most organisms proliferate with great rapidity in a favourable environment. It has been stated that a bacillus may attain its full growth and divide in less than half an hour, and at this rate one individual would reproduce itself nearly seventeen million times within twelve hours, and 281,475,000,000,000 times in twenty-four hours.

Spores.—The production of spores and the properties with which they are endowed are among the most important facts regarding bacteria. Discovered at first in some of larger size, the process is now known to be common to many bacilli and to some spirilla. It is doubtful if any of the cocci ever form true spores. But from known facts in the life-history of many species in which the existence of spores is not proved, there is a possibility that in them also there exists a like capacity, given favourable conditions of life. Spore-formation is to be regarded as a resting stage in the life-history of a bacterium, which, therefore, may pass through two stages, (1) a vegetative, spore-free stage in which rapid multiplication may occur, producing other vegetative forms, (2) a spore or resting stage in which no reproduction takes place, for each organism produces only one spore, and each spore, when it germinates, gives rise to a single vegetative form.

The conditions of spore-formation are somewhat peculiar, and appear to depend upon a combination of circumstances, some of which are adverse and others conducive to vegetative growth and development. For example, sporulation does not in most instances occur until vegetative growth has been arrested by some change in the medium, probably due rather to the formation of substances inimical to growth than to the exhaustion of the nutriment. But this alone is not sufficient, for spores need not form unless the temperature is

maintained within favourable limits, and the limits for spore-formation are even more restricted than those for vegetative growth, though the optimum temperature in each case practically coincides. Free oxygen also appears to be essential to some forms, and even in certain anaërobic organisms sporulation is assisted by its presence. It cannot therefore be held that spore-formation occurs only in the absence of the optimum pabulum; it is more properly regarded as a normal phase in the life-history, occurring especially in certain favouring conditions of growth.

The mode of spore-formation can best be studied in some of the larger bacilli, such as *B. subtilis* or *B. anthracis*. Within the protoplasm of the vegetative cell, and usually towards one end, there appears a minute rounded granule of higher refractive index which gradually enlarges at the expense of the parent cell until it becomes a mature spore. The spore is always smaller than the original cell, and is apparently derived from condensation and chemical alteration of its protoplasm. This method of spore-formation is known as 'endogenous,' and the bacteria in which it occurs are spoken of as *endosporous*. In some cases (e.g. *B. anthracis*) the parent cell soon becomes granular and shrunken, stains more faintly, and finally disappears, so that the spore is left enclosed in the shrivelled remains of the original cell-envelope. In other cases (e.g. *B. tetani*) the protoplasm of the bacterial cell may show little alteration long after the spore has been formed. Swelling may and frequently does take place at the site of the spore, so that the organism may appear beaded, and the swelling may be so considerable that the diameter of the spore may be twice as great as that of the cell, or even more (e.g. *B. tetani*). This appearance is apt to be exaggerated owing to the different refraction of the spore and the cell-protoplasm.

In form spores are usually ovoid, more or less elongated, sometimes nearly spherical. In structure they consist of a highly refracting protoplasmic mass with great endowments of vitality and peculiar staining-reactions, surrounded by a capsule or cell-wall resembling that of the parent cell but of greater resisting capacity. Their staining-reactions differ from those of the cell-protoplasm, and may do so to a remarkable degree. Solutions which stain ordinary bacteria do not stain the spores; but by selective staining spores may take on a different colour from the rest of the cell (*vide infra*). In one of the common bacteria of water (*B. erythrosporus*) the unstained fresh spores normally show a definite colouration of a reddish tinge.

When placed in conditions favourable to vegetative life, spores begin to *germinate* and reproduce cells like those from which they originated. The process begins by the spore losing its high refraction, and continues by its gradual expansion to the size and form of the vegetative cell. The spore-capsule may be ruptured in various ways, sometimes being torn right across so that at each end of the growing cell part of the membrane appears as a cap, sometimes splitting longitudinally or at one end only. More rarely the capsule is simply stretched and absorbed by the expanding cell within. As growth advances movement appears in motile forms, and then follow multiplication and grouping of the vegeta-

tive forms, culminating later in spore-formation. Often only a few hours elapse between the first onset of germination and active vegetative growth.

Another form of spore-formation has been described in certain species which do not produce endospores, e.g. *Spirillum cholerae*, *streptococcus*, &c. According to this view certain of the vegetative cells pass into a resting stage and adopt the rôle of spores. They are then known as *arthrospores* (Hueppe). Structurally they may be of much the same form as the ordinary vegetative cell, or some modification of it. Functionally they are supposed to represent a more permanent condition by means of which the species is propagated, and from which subsequent germination may occur. They are also supposed to have greater powers of resisting adverse influences than the ordinary vegetative cell. It is doubtful if such a degree of specialisation of individuals ever occurs among the lower bacteria; and, indeed, all the known facts regarding the so-called arthrospores are consistent with known variations in morphology and biology among different individuals in the same culture.

Classification of Bacteria.—Many attempts have been made to arrive at some satisfactory division of bacteria, but hitherto with very limited success. The difficulty arises in great measure from defective knowledge of their life-history and of the variations which they may show in different conditions of growth. Most of the attempted classifications are valueless and are also unscientific. The only true basis is, of course, a botanical one, and such properties as the production of colour, of fermentation, or of disease are useless except as indicating provisional distinctions. The nomenclature usually adopted is founded on certain morphological data—chiefly the form of the cells and the arrangement commonly seen in their growth—but it must be understood that the names given are merely convenient appellations and not scientific distinctions. Reference has already been made to the division of bacteria into higher and lower forms.

1. The higher forms are characterised by greater structural independence of the elements and greater functional specialisation. They include such forms as *Beggiatoa*, *Thiothrix*, *Crenothrix*, *Cladothrix*, and *Streptothrix*. For more detailed information the article on ACTINOMYCOSIS may be consulted. See also STREPTOTHRIX.

2. The lower forms are divided into three main groups according to the form of the cells. (1) *Cocci* or *micrococci* consist of rounded or ovoid cells, and are subdivided according to their most usual grouping. Thus *diplococci* are formed when after fission the cells tend to remain in pairs; *tetrads* when after fission in two planes at right angles they are arranged in groups of four; and *sarcinae* when after fission in three dimensions cubical masses of eight are formed. *Streptococci* consist of cells forming single rows or chains of varying length, and *staphylococci* of cells forming irregular groups like bunches of grapes, all depending on the mode of fission and degree of subsequent cohesion among the individuals. (2) *Bacilli* include those cells of an elongated rod-like form, whether straight or slightly curved, and whether single or in filaments. Sometimes the term *bacillus* is restricted to the motile forms, and bacterium

applied to the non-motile (*Migula*), or, again, bacilli are regarded as characterised by endogenous sporulation and bacteria by its absence (Hueppe). (3) *Spirilla* also consist of cylindrical cells in which the curvature is more pronounced, either in the form of short rods with a single curve, as in the spirillum of cholera, or in the form of long filaments with several curves, as in the spirillum of relapsing fever. The terms *vibrio* and *spirochete* have also been introduced to distinguish degrees of curvature (Flügge), presence and characters of flagella (*Migula*), and relation to spore-formation (Hueppe). Such terms are of no practical value, and the possibilities of confusion which they introduce are sufficiently obvious.

Constancy of Species and Variation among Bacteria.—Modern bacteriology postulates the constancy of species among bacteria, and all known facts are in harmony with this conception. Moreover, direct attempts to transform one species into another have met with no success; even such closely allied forms as the typhoid- and colon-bacilli are not interchangeable, nor can the cholera-spirillum be transmuted into other species of spirilla.

Within certain limits, however, morphological, biological, and pathogenic variations are possible and indeed common among different members of the same species in different conditions. Morphological variations are not infrequent, particularly in regard to size; difference in shape may become extremely marked in those bacteria which show involution-forms, and most of the higher forms exhibit cyclical changes in the course of normal development and growth. Flagella are usually absent at some stage of the life-history of motile organisms, and many other characters may undergo change. Biological variations are still more common, and depend chiefly on varying conditions of growth. Thus differences are seen in rate of development, in appearance of cultures, in production of colour, in fermentative effects, and in power of resistance. The capacity for spore-formation may be temporarily or even permanently lost by exposure to certain influences. Most common of all is variation in the pathogenic properties of bacteria according to the attenuation or intensification of their virulence.

On the other hand it must be observed that among members of what was originally regarded as one species, differences so profound may be met as to suggest a group rather than a single species. Thus *Streptococcus pyogenes* has been regarded as a species distinct from *Streptococcus erysipelatis*, and the term *B. coli communis* has been held to include several closely allied species. Without discussing such questions fully it may be permissible to say that all recent evidence points rather to considerable potential variation within definite species than to a multiplicity of slightly differing and ill-defined species.

Conditions of Growth and Vitality.—Certain conditions are essential to bacterial life, while others have a deleterious effect. It is important to note that within certain limits growth may be inhibited while vitality remains unimpaired or is only modified, so that conditions which arrest growth and development do not necessarily destroy bacteria. Different species present great variety in their power of resisting adverse conditions, and even in the same species different organisms may show marked variation in resisting capacity. When spores are present, the capacity for resistance is enormously increased,

as compared with that of the corresponding vegetative forms.

Nutritment.—Most forms of plant-life obtain the essential elements of their food-supply from very simple chemical combinations, e.g. carbon from carbon dioxide, nitrogen from nitrates, &c. But most bacteria feed and grow on the more complex organic substances that constitute the tissues of plants and animals. All the pathogenic bacteria are not only capable of deriving their nutrition from the highly complex proteid diet that animal tissues and fluids afford, but they grow best within the body of the living animal. They are therefore essentially parasitic in character. But nearly all the pathogenic forms are also capable of a saprophytic existence outside the living body, and for growth and development in these circumstances they require the presence of some proteid or carbohydrate substance. Hence in the preparation of artificial culture-media (*vide infra*) such material must be supplied. A great host of microbes that are rarely or never parasitic lead a saprophytic existence in effete animal and vegetable products which they resolve into more primitive chemical compounds. The great majority of bacteria, therefore, require at least a trace of some organic substance on which to live, but many saprophytic organisms can and do thrive on purely inorganic materials. Reference has already been made to the remarkable powers of certain bacteria in the soil, not only of elaborating ammonia and nitrites into assimilable nitrates for the maintenance of plant-life, but even of fixing free nitrogen and restoring it to the general nitrogenous circulation.

When the food-supply is deficient or unsuitable, growth is arrested, and if these conditions persist, either the bacteria die or sporulation occurs, and in this form their life is prolonged. An important means by which the pabulum is rendered unsuitable is by the diffusion into it of the products of bacterial growth. On artificial media an organism may at first grow luxuriantly, then cease growing, and finally die or spore, not because the pabulum has been exhausted, but because deleterious substances have been formed by its own activity.

But the medium in order to be adapted for bacterial life must also contain a sufficiency of moisture, and the effect of drying is to deprive the organism of an element essential to growth and to vitality. Desiccation not only arrests development, but quickly kills most vegetative forms, though spores may be kept in a dry condition for months or years. Among the vegetative forms there are very pronounced differences in their capacity for resistance; some, as the spirillum of cholera, being destroyed by a few hours' drying, whereas others, and notably the bacillus of diphtheria, may resist drying for weeks or months.

Again, most organisms grow best on a medium that is slightly alkaline to litmus, and the slightest trace of free acid is sufficient in many cases to arrest development (e.g. of the cholera-spirillum). Hence the reaction of the medium is also an important factor in determining the conditions of growth.

Heat.—A suitable temperature is one of the most important conditions for the growth and development of bacteria, and heat is also one of the most potent agencies in modifying or destroying their vitality. The same agency which is essential to growth is also one of the most effective germicides. For any organism there is an optimum temperature at which growth takes place most abundantly, and

there are also upper and lower limits of temperature beyond which growth ceases. The optimum temperature for vegetative growth varies considerably in different organisms, and three main groups may be recognised. (1) The pathogenic bacteria which are definitely parasitic grow best about 37° C.—the normal blood-temperature—or in other words the 'body temperature.' For many such organisms the limits of temperature consistent with growth are very restricted, so that development is arrested at a point a few degrees above or below the optimum. Thus the temperature limits of growth for the pneumococcus and diphtheria-bacillus are about 20° C. or 22° C. to 42° C., for the gonococcus and influenza-bacillus 25° C. to 42° C., and for the tubercle-bacillus 28° C. to 42° C. For others the range is wider, and growth may readily take place at lower temperatures. Thus the limits for the anthrax-bacillus are about 12° C. to 45° C., for the typhoid-bacillus 9° C. to 42° C., and so on. It has been already noted that the limits within which sporulation may occur are even more restricted. Anthrax-bacilli, for example, do not spore below 18° C. or above 42° C. (2) Those bacteria which are normally saprophytic, being concerned in processes of fermentation and decomposition, grow most actively at a lower range of temperature, usually from 18° C. to 22° C. as the optimum—a warm summer temperature, or, as it is sometimes called, the 'room-temperature.' (3) A remarkable group of organisms, known as the thermophilic bacteria, thrive best at such unusually high temperatures as 60° C. to 70° C.

Beyond the points at which growth ceases, there is a variable range of temperature within which the vitality is impaired but not destroyed. In this intermediate condition many vital processes and activities become modified and deranged. Thus the production of colour, acids, toxins, &c., may be altered or arrested, the capacity for spore-formation may be lost, and the virulence of the organism may be markedly attenuated. Temperatures above the limits of growth are probably more effective in producing these changes than those below; in other words excess of heat appears to exercise a more prejudicial effect than mere deficiency.

At certain temperatures the effect of heat is to destroy bacteria. In estimating the lethal effects of any temperature the duration of exposure must also be considered, as a brief exposure to a high temperature may be more destructive than a longer exposure to a lower temperature. Obviously too a lethal temperature is such as to destroy all the individuals exposed to it, so that, when they are subsequently transferred to a suitable medium, no growth whatever takes place. A temperature which is lethal to vegetative forms may be resisted by the same organism in a spored condition. Hence there may be stated for any organism the lethal effects of low and of high temperature for exposures of fixed duration both in the vegetative and in the spore-form. In regard to low temperature, however, it is difficult to determine the freezing death-point, owing to the occurrence of physical changes in the medium and mechanical pressure-effects, but many organisms, even in the vegetative form, may be kept for some time below the freezing-point of water without being killed, e.g. those of cholera, anthrax, &c. The minimum lethal temperature for definite exposures at high temperatures varies greatly for different organisms, and for the same

organism in different conditions. Most spore-free bacteria are destroyed at 60° C. in less than half an hour, and at 100° C. in a few minutes, e.g. the organisms of cholera, typhoid fever, diphtheria, plague, &c. A few organisms that are not known to spore may survive even higher temperatures: thus the *Staphylococcus pyogenes aureus* withstands 80° C. for half an hour before death occurs, and the *Bacillus tuberculosis* has much the same powers of resistance. When spores are present, even 100° C. may be withstood by some for a few minutes, by others for more than an hour.

Alternations of temperature are very prejudicial to bacterial life, although the upper limit may not be high. Repeated exposure to a temperature of less than 60° C. for an hour daily will destroy all organisms, whether spored or not, within a week, and alternate freezing and thawing have a like effect.

These data have reference to the effects of heat on bacteria in a normal moist environment. In a dry condition they can resist much higher degrees of temperature. Even vegetative forms may survive 100° C. for an hour, and spores may withstand 140° C. for several hours.

Oxygen.—Most known species grow best in the presence of free oxygen and are therefore termed *aërobic* bacteria or *aërobes*. Of these some are strictly aërobic, do not grow in the absence of oxygen, and are known as obligatory aërobes; but the majority, while growing best in the presence of oxygen, may also grow in its absence, and are known as facultative anaërobes or as being capably anaërobic. Most of the pathogenic aërobes belong to the latter group. Many organisms, however, thrive best in the absence of free oxygen and are termed *anaërobic* bacteria or *anaërobes*. Here also some are strictly anaërobic while others are capably aërobic, and the more important pathogenic anaërobes, as the bacilli of tetanus and of malignant œdema, belong to the former group. But even obligatory anaërobes may grow in the presence of air when associated with aërobic organisms, and it is supposed that the latter produce substances which render this possible. Moreover some bacteria may be aërobic in certain conditions and anaërobic in others, for thermophilic bacteria thrive aërobically at high temperatures, but only anaërobically at lower temperatures (Rabinowitsch).

The chief means taken to exclude oxygen from cultures of anaërobes are (a) replacing oxygen by an indifferent gas, such as hydrogen or nitrogen, (b) adding some reducing agent to the medium, such as glucose or formate of sodium, (c) using deep tubes of agar or gelatine. It is often advantageous to combine these methods. Further the gaseous products of metabolism which frequently appear in artificial cultures of anaërobes may afford them protection against injurious oxygen-tensions in the media.

Light.—Direct sunlight has a most prejudicial effect on the vitality of bacteria, even when spores are present, and, if the exposure be sufficiently prolonged, its action is germicidal. The violet and ultra-violet rays are the most potent, and their effect is independent of the action of heat, but is conditioned by the presence of oxygen and of moisture. Diffuse daylight and the electric light have similar but less pronounced effects, while the Röntgen rays have not been shown to produce much change.

Chemical agents.—Many chemical substances may

inhibit the growth and development of bacteria, and are known as *antiseptics*; many others have a destructive action and are known as *disinfectants* or *germicides*, but most bodies that are classed as antiseptics are also bactericidal. Among inorganic substances the salts of the metals of high atomic weight (Ritchie) have the most powerful germicidal action, especially the perchloride and periodide of mercury. Among organic bodies the members of the aromatic series, of which carboic acid is a typical example, take highest rank as disinfectants.

MODES OF STUDY.—*Introductory.*—The complete study of any microbe demands a long and technical investigation in the pursuit of which many different methods and processes must be adopted. In all essential particulars the main steps of such an inquiry are the same for all bacteria, but the details vary widely with different organisms. When a tissue or fluid or other material suspected to contain bacteria is submitted for examination, one of the most important points is the *preparation and staining of specimens for microscopic work*. Not only should cover-glass films be made and suitably stained, but unstained moist films must also be examined to determine motility and other characters associated with bacteria in a fresh condition. Sections of tissues also show not only certain characters of the bacteria, but especially their site and relation to the tissue-elements and the processes of tissue-reaction to microbic invasion. The significance of the microscopical examination, however, is less than might be supposed, for histological characters, even when aided by special staining-reactions, do not afford a criterion for discriminating between allied forms. Nevertheless, when these characters are very definite and when the organism is found in constant association with a peculiar change, as in the case of the tubercle-bacillus, its identification in the tissues is comparatively easy.

Fortunately in the case of a large number of micro-organisms there is available a far more perfect mode of study, that of *cultivation or pure culture*, in other words the study of an organism growing outside the body on some artificially prepared medium and isolated from all other species. An incalculable advance on previous bacteriological research was made when this method was introduced; for it was found that by taking advantage of certain conditions of growth not only could a microbe be separated from all others, but that in suitable media successive growths or subcultures could be perpetuated through a long series of generations and maintained in a pure state. It is impossible to exaggerate the importance of this discovery in the advance of bacteriology. By the study of pure cultures there were revealed many morphological characters previously obscure or entirely unsuspected, the physiology and biology of bacteria became for the first time amenable to study, the chemical products of bacterial growth and activity were disclosed, and the way was cleared for the whole vast subject of the experimental inoculation of animals with pure cultures or their products and the acquisition of immunity. By culture, especially when aided by microscopic study, the recognition of various forms becomes more definite and certain; for each organism possesses its own peculiar characters, especially when grown upon or in semi-solid media. These characters comprise the form of the mass, the colour, rate of growth, results and effects upon the nutrient media, the relation to the presence or

absence of oxygen, the production of acids, indol, and other substances, and the capacity of growth on different media and at various temperatures. They may vary for the same organism in different media, and when taken together constitute almost absolute distinctions of most of the various known forms. By the aid of a lens the earliest groups and colonies may be studied, and will often be found to branch and grow in a characteristic way.

In certain groups of bacteria, however, several forms are so closely allied both in morphological and in biological characters that microscopical and cultural distinctions alone fail to afford more than a reasonable presumption of identity. In the case of the *Bacillus diphtheriae*, for example, it is known that other allied and relatively innocuous forms exist, which under the microscope and in cultures are practically indistinguishable, and the same is true regarding the *Spirillum cholerae* and others. Hence any inference based on such data must in certain cases be made with caution until another mode of investigation has been undertaken—the *inoculation of animals* (p. 132).

I. Cultivation of Bacteria.—It is obvious from what has been said that the most essential part of bacteriology is concerned with the study of pure cultures. Hence the means of obtaining them is of the first importance. But micro-organisms are practically ubiquitous, and are present in the air, in water, and in the dust covering all apparatus and utensils, so that every object and material that is to come into contact with bacteria must first be freed from all such adventitious germs by processes of *sterilisation*. And, further, all media must be protected from subsequent contamination by methods adequate to the *exclusion* of extraneous organisms. Moreover in natural processes of infection it is only in certain tissues and in a few conditions that the specific bacteria are found entirely free from admixture with other species, and there is additional risk of contamination when the tissues are obtained after death. Hence methods of *isolation* are required in order that any one organism may be separated from all other varieties that may be accidentally or otherwise associated with it. But an essential preliminary to all methods of isolation and cultivation is the preparation of *nutrient media* in which the growth of bacteria may take place, and this nutriment must be available in such conditions of moisture, temperature, &c., as conform to the special biological requirements of the organism. The study of pure cultures accordingly necessitates: (1) methods of sterilisation and exclusion; (2) preparation of nutrient media; (3) isolation of pure cultures; and (4) maintenance of cultures in conditions adapted for vitality and growth.

Methods of Sterilisation.—Any agency which can destroy bacteria and their spores will render a material sterile, and the most potent of such agencies are either chemical or thermal. Mechanical processes also may be employed to remove bacteria from fluids, as in the separation of organisms from fluid media by special methods of filtration. Obviously all these agencies are not equally suitable in any given case. It is often necessary not merely that adventitious bacteria should be destroyed, but that the apparatus or medium should be left in such a condition as not to interfere with the vitality and growth of the organism which it is desired to cultivate. Chemical disinfectants, therefore, are only of limited utility in the preparation of material for

bacteriological work. See ANTISEPTICS; and DISINFECTION.

The agency which is most effective as a germicide and which leaves behind no deleterious influence is heat. Hence, where possible, sterilisation is best effected by heat or by alternation of heat and cold. Heat may be conveyed either by hot water or by steam at various temperatures, and in this form is far more powerful than when conveyed by dry air at the same temperature.

Methods of Exclusion.—The exclusion of all external organisms is effected mainly in two ways: (a) by sterilised cotton-wool plugs; (b) by the action of gravity.

Preparation and Uses of Culture-Media.—The considerations which regulate the preparation of media suitable for the growth of bacteria outside the living body include an adequate supply of pabulum, a sufficiency of moisture, a suitable reaction, the presence of elements essential to growth, and the absence of inhibitory influences. Such media vary greatly with the varying needs of different organisms, but it is possible roughly to classify those in common use.

(1) *Media containing body-fluids in a natural or only slightly altered condition* are prepared from blood-serum, exudations into serous cavities, aqueous humour, milk, urine, &c. They approximate most closely to the conditions of nutrition during the parasitic stage of bacterial life, and all pathogenic organisms grow best on them. Delicate organisms, such as the pneumococcus and influenza-bacillus, with little saprophytic vitality, may not grow at all on more artificial media. For such organisms 'blood-agar' is also invaluable, and is prepared by smearing the sloped surface of ordinary agar (*vide infra*) with a drop of sterile blood (Pfeiffer).

(2) *Artificial proteid media* are nearly all derived from a watery extract of the flesh of the ox, horse, sheep, calf, or fowl. Not only do most pathogenic organisms grow well on them, but the growths display a greater number of specific cultural distinctions than on other media. With this meat-extract as a basis, fluid media are prepared by the addition of peptone and sodium chloride, and the result is known as *peptone-broth* or *bouillon*. Its most important use is in the growth of organisms for separation of toxins and other soluble products by subsequent filtration. Semi-solid or gelatinised media have the same composition as bouillon with the addition of gelatine or agar-agar: the former are known as *peptone-gelatine* or *nutrient gelatine*, the latter as 'ordinary' agar or agar-agar. The disadvantages of gelatine media depend upon the relatively low melting-point of gelatine, which restricts its use to the cultivation of the more vigorous organisms which can flourish at the ordinary room-temperature from 18°C. to 22°C. But for such organisms there are certain outstanding advantages from the characteristic appearances which most cultures present, among which may be noted the presence or absence of liquefaction, the form of the surface-growth and that along the needle-track in stab-cultures, and the characters of the superficial and deep colonies in gelatine plates. Agar-media possess one great advantage in the fact that they can be incubated at the body-temperature without melting; hence, a greater number of bacteria can be successfully cultivated on them. But there is a certain sameness in the appearance of the growths on agar as compared with the varied cultural features of the corresponding growths on gelatine.

For special purposes various substances may be added to bouillon, gelatine, and agar media—e.g. glycerine for the growth of the tubercle-bacillus, glucose and formate of sodium for anaerobes, lactose for testing fermentative effects, and litmus for indicating the production of acids.

Neutralisation of media derived from meat-extract. The reaction of the crude meat-extract and its derivatives is invariably acid, owing to the presence of organic acids, amphoteric organic bodies, and acid phosphates. The usual mode of neutralisation is to add a few drops of a solution of sodium hydrate or carbonate until the mixture becomes just alkaline to litmus. Such a medium, however, is still acid to a more delicate indicator, such as phenolphthalein, owing to the presence of dibasic sodium phosphate (Na_2HPO_4), which, being alkaline to litmus, has not been neutralised. As the amount of this salt varies, the degree of acidity is unknown and inconstant. To obviate this objection endeavours have been made to obtain media of constant or 'standard' reaction. By the addition of decinormal and normal solutions of sodium hydrate the medium is first rendered neutral to phenolphthalein, and then 'standardised' by the addition of one and a half per cent. of a normal solution of hydrochloric acid—the reaction being still slightly alkaline to litmus. It is found that the optimum reaction for the growth of most organisms is afforded by a medium that is slightly alkaline to litmus and slightly acid to phenolphthalein (Fuller, Eyre, and others).

(3) *Artificial carbohydrate media* comprise chiefly boiled potato and bread-paste. The appearances of growths on potato often reveal characteristic differences between allied species, but the reaction of the potato must be noted, and in special cases modified. Bread-paste is most useful for the cultivation of moulds, torulae, and the chromogenic bacteria.

(4) *Other artificial media* include vegetable infusions and various chemical combinations, such as Cohn's fluid, Pasteur's original solution, Winogradsky's media for the culture of nitrifying organisms, &c. Many are of merely historical interest.

Methods of Separation and Isolation.—(1) *Repeated dilution of the bacteria and mechanical separation of the colonies.*—This is one of the most useful and most commonly employed of all methods, and depends upon a mode of 'plate-cultivation' introduced by Koch. The principle is, that single organisms in suitable conditions give rise to single colonies of the same organism, and that accordingly, if the colonies are sufficiently separated, pure cultures may be obtained from each.

(a) *In ordinary aerobic conditions* the more important methods include Koch's gelatine plates or Petri capsules, Esmarch's roll-tubes, agar plates, successive strokes on agar-surfaces, &c. *Gelatine plates* are prepared by taking three or four tubes of melted gelatine, inoculating the first from the suspected material, then the second from the first, the third from the second, and so on. The fluid contents of each tube are poured out into a separate plate and allowed to solidify. Colonies may appear very abundantly in the first plate, less in the second, and still less in the third; and from the colonies thus separated, pure cultures may be made. *Esmarch's roll-tubes* are prepared in the same way, but instead of being emptied into plates, the tubes are rolled under a stream of cold water, so that the gelatine solidifies on the wall of each tube. *Agar plates* are used in the manner above described, and

can of course be incubated at the body-temperature. *Successive strokes on agar-surfaces* are made by charging a platinum needle with the suspected material and gently stroking the surface of three or four agar tubes or plates, without recharging the needle.

(b) *For anaerobic organisms* the method is essentially the same so far as the processes of dilution and mechanical separation are concerned. Hence gelatine and agar plates and gelatine roll-tubes are all useful so long as means are taken to exclude oxygen. Vignal's method is frequently of value. Three or four tubes of melted agar are successively inoculated and their contents sucked up into separate lengths of quill glass tubing, the ends of which are sealed in the flame of a Bunsen-burner. Separate colonies appear at various intervals, and may be obtained by breaking the glass over them.

(2) *Inhibition of immaterial growths by various agencies.*—Advantage is sometimes taken of the fact that conditions which arrest the growth of some bacteria may only slightly retard that of others. Thus phenolated media have been employed in the isolation of typhoid-bacilli from the stools.

(3) *Separation of spores by the destruction of spore-free bacteria.*—If spores are present in the causal organism, they may be freed from any vegetative forms associated with them owing to their greater powers of resistance. Thus a short exposure to a temperature of 80°C . to 100°C . will allow only spores to survive. This method is often combined with others, and is specially useful for isolation of anaerobes.

(4) *Separation by inoculation of susceptible animals.*—In cases where there is some special difficulty in the way of obtaining pure cultures it may be possible to isolate the organism in the blood or tissues of certain animals. Thus the pneumococcus, an organism of extremely delicate growth, may be isolated in the blood of a rabbit, and the tubercle-bacillus, which is characterised by its extremely slow growth, may be cultivated from certain viscera. The glanders-bacillus too may be readily isolated by similar means.

II. Microscopic Examination of Bacteria.

In the fresh unstained condition bacteria may be examined in a variety of ways. The appearances of colonies in gelatine or agar plates, test-tubes, &c., are best seen under comparatively low magnifying powers. The actual development and mode of growth of any organism should be studied in hanging-drop cultures. The characters of living bacteria and many vital phenomena in which they are concerned may be investigated by means of fresh films examined in fluids under a cover-glass, a warm stage being employed when necessary. By this means the grouping of the cells, the presence or absence of motility, and the processes of chemotaxis, phagocytosis, and agglutination may be conveniently studied.

Permanent preparations are obtained after some preliminary process of fixation with subsequent staining of the bacteria; and these processes are applied chiefly to two forms of preparations, (1) films, and (2) sections of tissue.

Methods of fixation: (1) *Film-preparations.*—Of all modes of microscopic study this is of widest application and of greatest value. Films may be made from almost any material containing bacteria,

and fixation is effected in many different ways according to the nature of the material in which the organisms are present and the special structural features to be examined.

Films from cultures.—Films are prepared from growths in solid media either by first making a dilute emulsion of the growth in a few drops of sterile distilled water, transferring a loopful to the cover-glass and spreading it out in a thin layer, or by first placing a loopful of water on the cover-glass and mixing with it a very minute quantity of the growth. The organisms should be so diluted as to render the film almost invisible. When growths occur in fluid media or in the water of condensation from solid media, films may be made by spreading a loopful of the fluid directly over the cover-glass. In any case the film is dried by heating over the flame of a Bunsen-burner at the highest temperature the hand can comfortably bear. The amount of heat required to thoroughly dry the film is usually also sufficient to fix it, but, if not, it may be passed two or three times quickly through the flame.

Films from animal fluids and tissues.—From pus, sputum, and other highly cellular fluids, films are best obtained by smearing a loopful over the cover-glass with as little manipulation as possible. Some parts will be found too thick for examination, but the thin parts between should suffice. In the case of watery exudations, e.g. ascitic and pleuritic effusions, and in the case of watery secretions, e.g. urine, any bacteria present are usually so scanty as to elude direct observation. The fluid should therefore be allowed to stand for several hours in conical glasses, or better, centrifuged and a loopful of the deposit then spread out over the cover-glass. From the solid organs and tissues films are prepared by gently rubbing the portion to be examined over the cover-glass. The fixation of the films thus prepared may be effected according to one of two methods named, (a) the dry, and (b) the wet, according to the initial step in the process. (a) In the dry method the films are fixed by gentle heat in the manner above described. In this way the bacteria are well preserved, but more highly organised structures, e.g. leucocytes and tissue-cells, are not so well seen. (b) In the wet method the film is never allowed to dry, but is at once placed in some fixing solution, the best being a saturated solution of mercuric chloride prepared by boiling this salt in a solution of sodium chloride (0.75 per cent.). In this the films remain from two to four minutes, and they are then washed in salt-solution and in spirit to remove all crystals of mercuric chloride. They are now ready for staining.

Films from blood.—Special methods of preparation and fixation are required. The skin having been thoroughly cleansed and rendered aseptic, a small puncture is made, and as much blood as will lie in the loop of a platinum needle is transferred to the centre of one cover-glass. Another cover-glass is placed above the first, and, if both are clean, the blood should spread in a thin film between them. They are then rapidly separated, and in the dry method they are dried by waving them in the air. In order to preserve the cellular constituents the film must be fixed either in a saturated solution of mercuric chloride for several minutes, or in a mixture of alcohol and ether in equal proportions for half an hour, or in the hot-air steriliser at 120° C. for the same time. The wet method of fixation is applicable to blood-films also.

(2) *Fixation of tissues.*—For the examination of bacteria this is best accomplished by placing thin slices in a saturated solution of mercuric chloride for twelve to twenty-four hours. The pieces of tissue are then transferred to methylated spirit, and finally embedded and cut in paraffin so that the section may be as thin as possible. A good result may also be obtained by direct fixation in methylated spirit or absolute alcohol. The full details of these various processes would occupy too much space to be given here.

Methods of Staining.—Owing to differences in their chemical constitution the various structural elements of the bacterial cell differ in their reaction to colouring agents, so that it is necessary to consider methods of staining as applied to (1) the cell-protoplasm, (2) the cell-envelope or capsule, (3) flagella, (4) spores.

(1) *The protoplasm of the bacterial cell* resembles the nuclear chromatin of the animal cell in showing a marked affinity for the basic aniline dyes, e.g. thionin and methylene blue, gentian violet, fuchsin, &c. The simplest form of staining reagent is a watery or alcoholic solution of one of these dyes, and many bacteria take up such a stain with great readiness and intensity, provided that a sufficient interval of time is allowed to elapse and a sufficient concentration of the stain is employed. But a more complex process is usually indicated. In the first place all bacteria do not stain with equal readiness, and some resist the action of staining substances to a marked degree. Hence it becomes necessary to make use of mordants which aid the penetrating power of the stain and tend to fix it in the bacteria. The mordants in common use include carbolic acid, aniline oil, tannic acid, and various metallic salts and alkalis. The effect of heat should be noted as accelerating and intensifying all staining processes, and the result of lengthening the duration of the exposure to any stain, or of increasing the strength of the solution, is much the same as would be produced by the addition of a mordant. In the second place, when bacteria are stained in sections of tissue or in films along with other cellular structures, the tissue-elements are apt to take up the stain so deeply as to obscure the organisms, and accordingly various methods have been devised to remove the stain wholly or partially from the tissues and leave the bacteria coloured. This may be effected by the use of suitable decolourising agents, among the more important of which are sulphuric and other mineral acids, acetic acid, clove-oil, alcohol in the form of methylated spirit or absolute alcohol, and warm water. Very frequently use is made of the combined action of more than one decolourising agent, just as more than one mordant may be employed. After decolourising it is usually advisable to counterstain the tissue-elements in such a way that their structure is shown in some colour different from that in the bacteria themselves. The combinations of stain, mordant, decolouriser, and counterstain are very numerous, and only a few of the more typical examples can be given here. Among the more important simple stains may be noted *carbol-thionin blue*, which consists of thionin blue (1 gramme) dissolved in 100 c.c. of a watery solution of carbolic acid (1 in 40). One volume should be diluted with three volumes of water before use. Stain for about five minutes, wash thoroughly in water, and, if necessary, decolourise in water slightly acidulated with

acetic acid. *Dilute carbol-fuchsin* is prepared by diluting Ziehl-Neelsen's carbol-fuchsin (*v. infra*) in ten volumes of water. Stain for about five minutes, wash, and, if necessary, decolourise in warm water. In *Löffler's methylene blue* 30 parts of a saturated alcoholic solution of methylene blue are added to 100 parts of a watery solution of potassium hydrate (1 in 10,000). Films may be stained for five minutes or more; sections for several hours, as they are not readily overstained, and, if required, can be decolourised in a weak solution of acetic acid.

Some bacteria lose the stain so readily that they may become decolourised in the process of dehydration with alcohol. To obviate this Weigert suggested that sections, after being stained in an alkaline solution of gentian violet, should be dehydrated with pure aniline oil, cleared in xylol, and mounted in balsam. Another method, applicable to sections cut in paraffin, was recommended by Greenfield and Muir in the previous edition of this article. The sections, which ought to be as thin as possible, are floated on the surface of a weak solution of the aniline stain, and the liquid is very gently heated. The sections become quite flat, and the stain is seen to penetrate into the tissue. After a few minutes they are washed well on the surface of water, placed on a slide, and allowed to dry. The paraffin is then removed by xylol and the section is mounted in balsam.

On the other hand many bacteria do not readily take up the stain but retain it with greater tenacity. For such organisms *Gram's method* may be used. The staining solution consists of 1 part of a saturated alcoholic solution of gentian violet in 10 parts of a saturated watery solution of aniline oil (or preferably 10 parts of a five per cent. watery solution of carbolic acid), and should be prepared just before use. Stain for five or ten minutes; wash in water; apply for about one minute Gram's iodine solution (iodine 1 part, potassium iodide 2 parts, water 300 parts), and again wash. Rapidly remove water with absolute alcohol (or methylated spirit); apply clove-oil for 10 to 30 seconds; rapidly remove clove-oil with alcohol, and at once wash in water. The sections or films should then have only a faint violet tinge. The best contrast stain is saffranin. Bacteria stained by Gram's method appear of a dark violet colour, sometimes almost black, while most tissue-elements and bacteria that lose their stain in Gram's method are stained red by the saffranin.

Tubercle-bacilli are particularly resistant to staining agents and correspondingly tenacious when stained. *Ziehl-Neelsen's carbol-fuchsin stain* contains basic fuchsin 1 part, alcohol 10 parts, a five per cent. watery solution of carbolic acid 100 parts. The stain is applied to sections or films, heated gently till steam begins to rise, and allowed to steam for three to five minutes. Decolourise in 20 per cent. sulphuric acid and wash thoroughly in water. The tissue should then have a faint pink tinge. Counterstain for two minutes in a saturated watery solution of methylene blue. The tubercle-bacilli appear bright red, the tissues and other bacteria blue. Leprosy-bacilli may be stained in a similar way, but, as they are more easily decolourised, only a five per cent. solution of sulphuric acid should be used.

(2) *Staining of capsules*.—In the pneumococcus, pneumobacillus, &c., capsules may be stained by the use of a special mordant containing tannic acid

(Richard Muir). The mordant consists of 2 parts of a twenty per cent. watery solution of tannic acid, 2 parts of a saturated watery solution of mercuric chloride, and 5 parts of a saturated watery solution of potash-alum. Films, which should be as thin as possible, are first dried gently over a flame; the mordant is applied for two minutes, and the film washed in methylated spirit and water. Then apply Ziehl-Neelsen's carbol-fuchsin and heat very gently for two to four minutes. Wash in water, re-apply mordant for half a minute, again wash in water, and finally stain in a saturated watery solution of methylene blue for about five minutes. Differentiate in methylated spirit until the thinnest parts of the film appear blue, dehydrate in alcohol, clear in xylol, and mount in balsam. In this way the organisms are stained red, the capsules blue.

(3) *Staining of spores*.—By ordinary methods of staining spores remain uncoloured, but they may be stained by a method similar to that described for the bacilli of tuberculosis and leprosy. The stain is carbol-fuchsin heated as before, but the sulphuric acid solution should not exceed 2 per cent. in some cases, though it may be 5 per cent. in others. Before counterstaining in methylene blue, it is usually advisable to apply either a saturated watery solution of alum or the mordant recommended in staining capsules. Spores should then appear red, while the rest of the organism is blue.

(4) *Staining of flagella*.—The methods commonly employed are those devised by Löffler, Van Ermengem, Pitfield, and Richard Muir, but unfortunately all give somewhat uncertain results. Richard Muir's modification of Pitfield's method has the advantage of relative simplicity, and is at least not more uncertain than the others. Two solutions are required, (1) a mordant composed of ten parts of a 10 per cent. watery solution of tannic acid filtered, five parts of a saturated watery solution of mercuric chloride, five parts of a saturated watery solution of alum, and five parts of Ziehl-Neelsen's carbol-fuchsin (*vide supra*); (2) a stain composed of ten parts of a saturated watery solution of alum, and two parts of a saturated alcoholic solution of gentian violet. The mordant keeps well for several weeks, but the stain should be freshly prepared. Both solutions are used unfiltered. A thin film of the growth is carefully prepared and gently dried. The mordant is applied and the film heated for about two minutes, washed thoroughly in water and gently dried. The stain is then applied and the same processes repeated of heating, washing, and drying. Before the final drying Gram's iodine-solution (*vide supra*) may be applied for two minutes in order to darken the stained flagella.

RELATIONS OF MICRO-ORGANISMS TO THE LIVING BODY.—It may now be accepted as an established fact that the healthy tissues and fluids within the substance of the body are free from microbes; but the surfaces, both external and internal, constantly teem with them in the most varied forms.

The mechanism, so to speak, by which this bacterium-free condition is maintained during healthy life has been the subject of much experiment and controversy. Since foreign particles of various kinds, much larger than microbes, can and do enter the lymphatics and blood-vessels of the air-passages, alimentary canal, and even the skin,

it is certain that microbes can also enter. Experiment has shown that even if large quantities of certain cultivations are injected subcutaneously or into the blood-stream, they rapidly disappear, and in some cases after a few hours they can hardly be detected in the blood, or even in the lungs, spleen, and kidneys, where they appear to be largely arrested. Those discovered are often in various stages of degeneration or decay, and sometimes many are contained in leucocytes and connective-tissue corpuscles.

According to some, it is principally by the activity of leucocytes and connective-tissue corpuscles that micro-organisms are destroyed. This view has been especially developed by Metschnikoff and his followers, who have alleged for some leucocytes the special rôle of 'phagocytes,' i.e. of ingesting, amœba-like, noxious foreign particles, and having as one of their highest functions the elimination of microbes.

That the freedom from organisms is not solely due to the leucocytes is shown by the fact that blood-serum and other materials, which are free from leucocytes, also exert a destructive influence upon microbes. The freedom from bacteria may therefore be regarded as due in part to the fact that the healthy fluids and tissues of the living body exert an antagonistic action to, or do not serve as a suitable soil for, the growth of bacteria. The chemical or physical nature of the antagonistic condition is a highly important question. That the antagonistic condition may be a very minute chemical change is suggested by the facts of immunity, natural or acquired, and modified susceptibility under variations of nutriment. See IMMUNITY.

During the last stages of life, and apparently also in some conditions of disease, the power of resistance may be so lowered that common bacteria are found in the blood, and penetrate more deeply into the tissues with which they are normally in contact, e.g. in the alimentary system.

III. Inoculation of Animals.—Inoculation of animals may be undertaken for many different purposes. Certain organisms may be isolated from contaminated material in the blood or tissues of appropriate animals; but the special object of this mode of study is to investigate the pathogenic effects of pure cultures and of the toxic substances produced by bacteria. These effects are extremely varied and depend upon several factors: as regards the *virus*, upon (a) its quantity, (b) its form, and (c) its virulence, and as regards the *animal*, upon (a) its susceptibility, and (b) the site of inoculation. Some of the difficulties attendant on this mode of study have already been alluded to in an earlier part of this article.

1. The *virus*.—(a) The *dose* or amount of the injection materially modifies the result. A small number of bacteria or a small dose of toxin may produce little or no appreciable effect, for within certain limits the tissues and fluids of the living body possess remarkable powers of overcoming and destroying microbes. In fact, bacteria may with impunity be introduced beneath the skin, into the peritoneal sac, or even into the blood-stream, in quantities that depend upon their virulence and the potential resistance of the animal. Introduced in greater numbers, bacteria begin to multiply within the animal body and so infect it. Moreover, the form of the resultant lesion may vary

with the number of organisms injected. A small dose of pyogenic cocci in the subcutaneous tissue may give rise only to a localised inflammation or suppuration, whereas a larger dose at the same site may allow some of the cocci to enter the blood-stream and so cause a fatal septicæmia or pyæmia.

(b) The virus may be introduced in a variety of *forms*, as living bacteria, as dead bacteria, or as toxic products alone. *Living bacteria* produce their effects by multiplying within the body, and there elaborating toxic substances which may have both a local and a general action. *Dead bacteria* of course cannot multiply, but may be carried to various sites and there give rise to localised lesions due to the action of intracellular ferments or toxins, e.g. dead tubercle-bacilli may give rise to nodules of granulation-tissue, which often show typical giant-cell systems. The *toxic products* of bacterial growth may be isolated, and when injected reproduce many of the pathogenic effects. In some diseases (e.g. diphtheria, tetanus, &c.) the most important lesions are due to the action of separable toxins, and are induced when toxins alone are injected. When living organisms are introduced, the amount of toxic substances generated by them within the body is indefinite and uncertain, but by the use of toxins freed from bacteria, more exact data are obtainable, since a definite dose of toxin will produce definite effects per unit of body-weight of animal.

(c) The *virulence* of the material injected has an even greater bearing on the ultimate result. Thus the *Streptococcus pyogenes* may have its virulence so intensified that a few introduced beneath the skin will cause a rapidly fatal septicæmia, while the same organism in an attenuated form may be injected in large numbers with only a slight local reaction. Modifications in virulence may be artificially accomplished. The most important means of exalting the virulence of an organism is that known as the 'method of passage.' It depends on the fact that an organism which has produced disease in one animal is thereby rendered more capable of reproducing the disease in another similar animal. Hence, by inoculating a number of such animals, one from another—in other words, by passing the organism through the series—its virulence may be intensified to a high degree. In certain cases, and more especially when its pathogenic powers are impaired, the virulence of an organism may be restored or exalted by injecting it along with cultures or products of other organisms. Thus, the typhoid-bacillus, which is usually non-pathogenic to the lower animals, may have its virulence so intensified by repeated injections along with sterilised cultures of *Streptococcus pyogenes* or of *B. coli*, that ultimately the typhoid-bacilli alone come to have a lethal effect. In processes of natural infection in man it is not uncommon for the action of one organism to be aided by that of another. Probably the virulence of one or of both is thereby increased, and the site of the local lesion rendered more favourable for the growth of the predominant microbe. As examples may be noted the frequent association of the *Streptococcus pyogenes* with the bacillus of diphtheria, and the presence of putrefactive organisms in many of the local wounds in tetanus. On the other hand virulence may be weakened or attenuated in many ways. After successive subcultures outside the body most organisms are found to have lost their original patho-

BARBADOES LEG—A form of Elephantiasis. *See* ELEPHANTIASIS.

BARBIERS.—A synonym for Beriberi. *See* BERIBERI.

BARÈGES, in France.—Thermal sulphur waters. *See* MINERAL WATERS.

BARTFELD, in Hungary.—Alkaline saline chalybeate springs, with iodine. *See* MINERAL WATERS.

BASEDOW'S DISEASE.—A synonym for exophthalmic goitre. *See* EXOPHTHALMIC GOITRE.

BATH, in Somersetshire.—Simple thermal and earthy waters. *See* MINERAL WATERS.

BATHS.—Baths may be regarded as *simple* and *composite* (*medicated*, *artificial*), and as liquid, vapour-, and air-baths. We shall consider them under these heads in the following description.

A. SIMPLE BATHS.—**I. Simple Liquid Baths.** The clothes by which the body is usually covered form a kind of thermal zone about the skin, the temperature of which remains ordinarily within a few degrees of 89° F. The skin therefore is thoroughly accustomed to this temperature, and an ordinary bath must be given at a decidedly higher or lower temperature, if much reaction be desired. Even however at neutral temperatures—say between 85° and 95° F.—a reaction may be obtained by mechanical stimulation of the skin, as in wave-baths and douches, or by drying the skin with a rough towel after the bath; in the case of mineral waters and medicated baths stimulating effects may likewise be obtained by the salts, carbonic acid gas, &c., contained in the water.

1. The Cold Bath.—By a cold bath is meant the immersion of the body in water below the temperature of 70° F. Anything below 50° is considered a very cold bath. The first effect of the bath is a sensation of cold, with slight gasping for breath. If the cold is intense and prolonged, there is a certain degree of numbness of the skin; while the pulse becomes small, and may become less frequent by ten to twenty beats in the minute, and there may be shivering. Owing to the constriction of the cutaneous blood-vessels the skin is pale, and the contraction of the unstripped muscle-fibres gives rise to the phenomenon of 'goose-skin.' These first effects of a cold bath may give place to the 'reaction' while the bather still remains in the bath, or only when he has left it. The pallor of the skin changes to slight redness, accompanied by an agreeable subjective sensation of warmth, easy breathing, and a feeling of comfort and capability for exertion.

The reaction is delayed in the weak and feeble, but takes place rapidly in the robust and strong, especially when accustomed to cold baths. In strong persons, who are in the habit of taking cold baths, the preliminary vaso-constriction and sensation of coldness are less marked than in others, whereas the reaction, together with the agreeable subjective phenomena which accompany it, occurs more readily. In irritable nervous subjects signs of reaction may sometimes be rapidly and readily obtained, though the reaction may be imperfect and too transient. In a given case the rapidity and kind of reaction depend on the temperature of the water, the length of the application, and the

accompanying amount of mechanical stimulation; it is greatly assisted by voluntary muscular action (such as swimming), and by friction to the skin before, during, or after the application. The reaction may be hindered, if the cold bath is of too long duration, or, if it has already occurred, it may pass off and give place to depression. The best reaction with the least loss of heat is generally obtained by cold applications of short duration, administered when the patient is hot.

The vascular and respiratory phenomena produced by a cold bath are generally considered to be mainly, if not entirely, due to reflex action. In persons who feel the loss of heat excessively, especially if preliminary warming by exercise be difficult, a cold bath or douche (which should of course be of very short duration) may be immediately preceded by a short warming application, such as a hot bath, a hot douche, or a hot vapour-bath. A preliminary hot bath with soaping renders the skin more sensitive, and facilitates the reaction. In suitable cases, when the organism can stand the abstraction of heat, and when the circulatory, respiratory, and digestive systems react sufficiently, treatment by cold baths should strengthen the heart's action, exercise the respiratory organs, increase the appetite, and aid digestion; while metabolism should be rendered more complete, and the elimination of waste products facilitated. The quality of the blood and the nutrition of the whole body should be improved, and the capacity for muscular and mental work should be increased.

2. The Warm Bath.—A warm bath of 96° to 104° F. produces no shock; it causes a moderately increased flow of the circulating fluids to the surface, augmenting the frequency of the pulse; and scarcely affects the respiration. There is not the depression or the excitement of a cold bath. It rather retards tissue-change. With a hot or very hot bath—from 104° to 114°, the central nervous and circulatory systems are more affected. The frequency of the pulse increases greatly. The respiration becomes anxious and quickened. The skin is in a hyperemic condition, and in many persons a free perspiration breaks out.

3. The Tepid Bath.—Tepid baths of the temperature of 85° to 95° F. are intermediate between cold and warm. Their effects seem to be confined to the peripheral extremities of the nerves, and they do not excite the nervous centres or the circulatory system. Neither the pulse nor the excretions and secretions are affected. As no heat is confined in the system or taken from it, there is no reaction, and the body-temperature is unaltered. A macerating action on the superficial epidermis can be obtained by prolonged tepid baths, similar to that effected by the prolonged tepid mineral-water baths of *Loèche-les-Bains* in Switzerland.

It need scarcely be added that drying and rubbing after a bath materially assist its action on the skin; or that, according to circumstances, it may be convenient to order a whole bath, a hip-bath, or a slipper-bath. The foot-bath is a very useful and convenient one, especially when some stimulant substance is added to the simple water. Wet packing and hot and cold affusion, whether as shower-baths or as douches, are referred to in the articles on DOUCHE, and HYDROTHERAPEUTICS.

The duration of a bath must depend on a variety of circumstances—for instance, on the age and constitution of the patient, on the nature of his malady,

and on the temperature of the bath. It may vary from a few minutes to many hours. A very hot or a very cold bath can be supported for a much shorter time than a tepid one.

ACTION AND USES.—Cold baths are indicated for the strong, for youth, and for manhood; warm baths for the delicate, for women, for early childhood, and for old age. Tepid baths are suitable for almost all constitutions, sexes, and ages. Cold baths may, in a general way, be considered tonic and bracing; they are useful when judiciously employed in many nervous affections, as in chorea and hysteria, and they are the best of all for general hygienic purposes. Of late years they have been specially employed in the treatment of pyrexia, and of the infectious diseases (especially typhoid fever) of which fever is a symptom (*see TEMPERATURE; FEVER; and HYDROTHERAPEUTICS*). The great value of warm baths, besides their hygienic value, as better detergents than cold ones, is in soothing and reducing excitement; in relieving spasms, such as colic and retention of urine; in the convulsions of children, combined with the affusion of cold water on the head; in cases of gout and rheumatism, and generally when action on the skin is desired. Where prolonged immersion is wanted, tepid baths are indicated, as in calming many chronic nervous disturbances, and in many cutaneous affections.

As to contra-indications, all baths, and especially prolonged baths, even when tepid, are not suited for the asthenic. Both hot and cold baths are to be avoided where there is a weak, fatty heart, or any tendency to apoplexy. No one should ever enter a cold bath when exhausted, and such baths are also contra-indicated when there is a tendency to congestion of internal organs. Under such circumstances a warm bath is usually both safer and more refreshing. The too long and too frequent use of hot baths is debilitating.

II. The Simple Vapour-Bath.—A vapour-bath is one in which the skin is exposed to the action of hot water presented in the form of vapour. The vapour-bath may be taken in a box with the head included or not; or in the more common form of the Turkish or Russian baths, where a large room is filled with vapour, and where therefore the vapour is inhaled; or by vapour obtained from a small and suitably constructed apparatus, which vapour may be diffused over the whole body or directed to a particular part. A very simple apparatus for the vapour-bath may be prepared by placing under a chair a shallow earthenware or metallic pan, containing boiling water to the depth of three or four inches, and from which abundant vapour can be obtained by placing in it one or two red-hot bricks. The patient sitting on the chair, surrounded by blankets and other suitable covering, will receive the full benefit of a vapour-bath. Vapour-baths produce profuse perspiration, and act in cleansing the skin much as hot-water baths do, only more powerfully. Vapour being a slow conductor does not act so fast on the body as water. Vapour-baths can be borne hotter than warm-water baths, but their use cannot be continued so long, as vapour interferes with radiation of heat from the body. In such baths a heat of more than 122° F. is not borne comfortably. The vapour-bath, though falling considerably short in temperature of the air-bath, raises the heat of the blood somewhat more. The great virtue of these baths lies in their sweat-producing properties. The

average loss of perspiration by the use of a Russian bath has been set down at from $\frac{2}{3}$ lb. to 3 lbs. In the Russian bath a slight degree of stimulation of the skin is caused by switching it with twigs of birch, and the alternation of depression and excitement of the cold bath is obtained by placing the patient, when in a state of profuse perspiration, under a douche of cold water. In Russia a roll in the snow sometimes takes the place of the final cold douche or plunge.

III. The Simple Hot-Air Bath.—There are two forms in which the hot-air bath is administered: according as the patient does or does not breathe the heated air. The action of the former closely resembles that of a vapour-bath, but differs from it in not impeding the respiration, as the latter does, by accumulation of moisture in the bronchial tubes. The lungs, instead of having to heat up the inspired air, are subjected to a temperature above their own. Hot-air baths favour the highest degree of perspiration; the moisture of vapour-baths somewhat opposes it, though in certain persons sweating commences more readily with moist than with dry heat. Very hot-air baths raise the temperature of the body by several degrees.

As the arrangements for vapour- and hot-air baths are practically the same (except that in the latter it is attempted to exclude all vapour from the *calidarium* or *sudatorium*, the hottest room), the following description of an ordinary hot-air bath, the arrangements of which are closely copied from the Romans, will answer for both.

The patient, after unclothing, first goes into the *tepidarium*, which has a temperature of 113° to 117° F., in which he remains until the perspiration bursts forth, which happens in from twenty-five to forty minutes. He next proceeds to the hottest room or *calidarium* (in which the air is heated by hot-air pipes which are inserted in the walls, to a temperature of 133° to 140° F.), and remains there until the perspiration runs down his skin, in twelve to eighteen minutes. An attendant then rubs off the perspiration with a woollen glove, and kneads all the muscles for four or five minutes. The patient next betakes himself to the *lavacrum*, where he has water poured over him of the temperature of 81° to 86° F.; then the whole body is soaped over, the suds are removed, and the patient goes to the *frigidarium*, where he lays himself on a couch and waits till his skin is completely dry. This may occupy twenty-five to thirty minutes, when the patient dresses and leaves the bath greatly refreshed.

Such is a brief account of these baths, the revived use of which is at present so general. The arrangements vary in detail. In all large baths of this kind, used by many persons, special care has to be taken that the arrangements for ventilation are sufficient. For ordinary purposes it is easy to furnish either vapour or hot-air baths. Different kinds of apparatus have been invented for this purpose, but they all have this in common, that the patient, placed in bed or on a seat, has the bedclothes or other covering secured from contact with him by the employment of a framework or cradle. Beneath this hot air or vapour is introduced, either directly or indirectly, from a suitable apparatus.

USES.—Both hot-air and vapour-baths are indicated when increased action of the skin is desired. They are used most for the cure of catarrhs, of neuralgic and rheumatic pains, and sciatica. They

are sometimes employed in the treatment of obesity, and are useful for general hygienic purposes, but are apt to be given too indiscriminately. Hot-air and vapour-baths are often locally applied with great advantage to a hand, or leg, or arm, in rheumatism or thickened joints.

Electric light has of late been much employed for administering both local and general hot-air baths. It has been maintained that owing to the action of the light as well as the heat, these electric light or 'radiant heat' baths have some peculiar effect of their own, and that they can produce sweating without accelerating the heart's action to the same extent as ordinary hot-air and vapour-baths. These questions have, however, not yet been settled.

The Sand-Bath.—We may here mention baths of sand. At the present time establishments for supplying them exist in various towns. They are a convenient way of applying dry heat either locally or generally, and are principally employed in chronic rheumatoid arthritis. Bags filled with heated sand (or salt) are useful in hospital and in domestic practice.

Carbonic-Acid Gas-Baths.—These should be likewise mentioned, though they are not much employed. The carbonic acid gas arising from mineral waters (as at Franzensbad and Marienbad) has usually been employed for the purpose. The patient sits thinly clad in an atmosphere of the gas, care being taken that the gas does not rise higher than the shoulders and that none of it is inhaled. A subjective sensation of warmth in the lower limbs, and the part of the body bathed by the gas, is produced; but the therapeutic value of this method of treatment is doubtful. Local baths and douches of carbonic acid have been employed for neuralgic and superficial inflammatory conditions.

B. COMPOSITE, MEDICATED, OR ARTIFICIAL BATHS.—A great variety of substances have been used in baths at different periods. We must confine ourselves to such as are at present in use and appear to be of real value, omitting even some that are employed, such as baths of iodine, of iodide of potassium, of iron, of fermented grapes, and of whey.

I. Composite Liquid Baths.

1. *The Sea-Water Bath.*—The average amount of salts in sea-water may be set down at 3 per cent.; this may therefore be considered a suitable strength for ordinary salt baths. The quantity commonly used in London hospitals is about 9 lbs. of salt to 30 gallons of water. Owing to the high price of sea-salt in inland continental places, various natural salts, some of them containing a comparatively small amount of chloride of sodium, have been suggested as substitutes; and also, for economy's sake, 22 to 25 gallons have been set down as a minimum amount of water for the bath of an adult. The value of these substitutes can only be determined by observing the degree in which they stimulate the skin. Apparently it does not matter much what particular salt is employed to produce the stimulation. A salt bath can of course be increased to any strength by the addition of what is termed 'mother-lye' (German 'Mutterlauge').

The chief uses of salt-water baths are as tonic remedies, especially for the young, when there is any tendency to scrofula or debility in convalescence from many diseases.

2. *Effervescent, Gaseous, and Artificial Nauheim*

Baths.—These baths have been considerably employed of late years, since the natural tepid effervescent salt baths of Nauheim have been much advocated in the treatment of certain chronic cardiac disorders. The bath-water may be charged with carbonic acid from cylinders of the compressed gas. The stimulating effect of gaseous baths is due chiefly to the mechanical action of the small bubbles of the gas on the skin. Two or three per cent. of common salt and two or three per thousand of calcium chloride should be dissolved in the bath-water, when it is desired to imitate the natural baths of Nauheim.

3. *Alkaline Baths.*—Alkaline baths may be made by adding 6 ounces of crystallised carbonate of sodium, or 3 ounces of carbonate of potassium, to 25 or 30 gallons of water. Alkaline baths are of use in a great variety of cutaneous affections.

4. *The Corrosive-Sublimite Bath.*—This is commonly made by adding 3 drachms of corrosive sublimate and 1 drachm of hydrochloric acid to 30 gallons of water. It has been occasionally employed in some skin-affections, and in secondary syphilis.

5. *Sulphuret of Potassium Bath.*—Baths of sulphuret of potassium are made by dissolving from 4 to 8 ounces of that salt in 25 to 30 gallons of water. A little diluted sulphuric acid is sometimes added. These baths have long been extensively employed in the treatment of cases of skin-disease in which the sulphur they contain is indicated.

6. *The Nitro-Muriatic Acid-Bath.* The nitric or rather nitro-muriatic acid bath—used by some in India and in England for liver-affections—is made by adding nitro-muriatic acid to water. The ordinary proportion is one ounce of acid to one gallon of water. The discolouring action on clothing makes a full bath of this kind inconvenient for domestic use, and it is best to take it in a bathing establishment. For the ordinary purposes of a foot-bath at home, the following directions are sufficient. The vessel must of course be of wood or earthenware. Four to six ounces of the acid are added to three gallons of water. This makes a strong foot-bath. The patient keeps his feet immersed for thirty minutes; and the bath is to be repeated every other day for two or three weeks. The axillæ, the groin, and the region of the liver are to be sponged with the acid solution. The bath causes slight tingling of the skin and a taste in the mouth, and is believed occasionally to produce salivation.

7. *The Bran-Bath.*—The bran-bath is made by boiling four pounds of bran in one gallon of water, straining, and adding the liquor to a quantity of water sufficient for a bath. Such a bath is useful in allaying irritability of the skin, and also in diminishing the stimulating effect of other baths.

8. *The Fucus-Bath.*—This is made by adding a decoction of seaweed, or the seaweed chopped up, to an ordinary bath; it will become more or less gelatinous if enough be added. Such baths go popularly by the name of *Ozone Baths*. They are useful in the same cases as sea-baths.

9. *The Mustard-Bath.*—An extremely useful stimulating bath is the well-known mustard bath, which is made by adding a handful or two of mustard to the ordinary hot bath. The foot-bath is its most useful form.

10. *Pine-Baths.*—Baths of the balsam of pine-leaves may be prepared extempore by making decoctions of the fresh leaflets at certain seasons; but the usual way is to add about one pound of the extract, which is prepared from the leaves, and is

everywhere for sale—at least in Germany. The extract dissolves in the bath, which is then ready for use; but of late it has been usual to add a small amount of an essence which is also prepared from the leaflets. It floats to the surface of the water, and attaches itself to the person on leaving the bath, and its aroma is grateful. These favourite baths are largely employed at bathing establishments in every part of Europe. They are slightly stimulant, and are much used in hysterical, rheumatic, and gouty affections, and also as an adjunct to the internal use of mineral waters.

It is scarcely necessary to add that, as a rule, all composite liquid baths should be of a temperature a little above the tepid; and that their strength, and the time that the patient is to remain in them, must be determined by the special circumstances of the case.

II. Composite Vapour-Baths.—Vapour-baths impregnated with *fir-balsam* are popular, and are considered to be more powerful in their operation than pine baths. The vapour which rises in making the decoction of pine leaves is conveyed to a box in which the patient is enclosed.

Aromatic vapour-baths may be given by making the steam of hot water pass through bunches of fresh aromatics (*conium*, *lavender*, &c.) before reaching the box in which the patient is placed. Such baths may be useful in hysteria.

III. Composite Air-Baths.

1. *Sulphurous Acid Bath.*—A valuable mode of applying sulphur in the form of a bath is by using its fumes—in other words, sulphurous anhydride. The patient is seated on a cane-bottomed chair, and his body is encircled with a cradle, over which oil-cloth is thrown, the head remaining uncovered. Sulphur is placed on a metallic plate, to the lower surface of which the flame of a lamp is applied, when sulphurous acid is disengaged.

2. *The Mercury- and Calomel-Baths.*—Very similar is the mode of applying the fumes of mercury. Under the chair are placed a copper bath containing water, and a metallic plate on which are put from 60 to 180 grains of the bisulphuret or of the yellow or red oxide of mercury. Spirit-lamps are lighted under the bath and under the plate. The patient thus experiences the effects both of aqueous and of mercurial vapour. At the end of five or ten minutes perspiration commences, which becomes excessive in ten minutes or a quarter of an hour. The lamps are then to be extinguished, and when the patient becomes moderately cool he is to be rubbed dry. He should then drink some warm liquid and remain quiet for a time (see *SYPHILIS*). Calomel, in quantities of from 20 to 30 grains, is administered in a similar manner, under the name of the *calomel-bath*. It may be given locally by a suitable apparatus.

IV. Electrical Baths.—Electricity is sometimes applied in association with baths or douches of water. See *ELECTRICITY IN MEDICINE*.

BERIBERI.—SYNON.: *Kakke* (Japanese).

DEFINITION.—A disease characterised by multiple peripheral neuritis, and presenting symptoms of paralysis, oedema, or both, varying with the kind and position of the nerves affected; tending generally to recovery, but frequently ending in death from implication of the nerves controlling or regulating the chief organs of circulation and respiration.

ETYMOLOGY.—Beriberi is a Cingalese word, and means simply 'a bad sickness,' or 'a sickness from which the patient is in danger of death,' the duplication of the syllables intensifying the meaning.

GEOGRAPHICAL DISTRIBUTION.—Beriberi is endemic in Japan, the Malay Peninsula, Sumatra, and many other places in the Eastern Archipelago; it is met with in epidemic form in China, Manila, many parts of India, Africa, and probably other tropical and subtropical countries; it breaks out as an epidemic occasionally on board ships; and of late years outbreaks have been reported from the West Indies, Fiji, Western Australia, the Richmond Asylum in Dublin, and other places where the disease was previously unknown, from which it would appear that a tropical climate is not absolutely necessary for the propagation of the poison.

ETIOLOGY.—The immediate cause of beriberi is not yet determined. It has been generally described as a disease of low-lying, damp localities, with associated conditions of overcrowding and defective sanitation, and there can be no doubt that its prevalence in epidemic form is favoured by these conditions, and that most or all of them are found in places in which the disease is endemic. Still the fact remains that no one of these conditions and no combination of any of them is necessary, and that beriberi will occur sporadically and as an epidemic in places in which not one of these conditions is present. This has been verified over and over again in the Straits Settlements, where beriberi has broken out and prevailed for a time in institutions which are neither damp nor low-lying, in which all matters relating to food have been carefully attended to, and in which no sanitary defect can be found. As regards the immediate cause of the disease, deficiency in nitrogenous food, some disease affecting rice, malaria, deficiency in fatty constituents of food, specific bacterial organisms, have all been from time to time put forward, and the writer, in over twenty years' experience of the disease, has been a convert to several of them in turn, but none of them has been found equal to accounting for all outbreaks of the disease. There can be no doubt that beriberi is caused by a specific poison, and the latest ideas seem to indicate that this poison is of the nature of a toxin, and that it is formed outside the body. Manson inclines to the opinion that the toxin or poison is manufactured in the soil, or in the houses and surroundings of beriberi spots; and it is certain that places, especially places which fulfil the conditions above mentioned as favourable to the spread of the disease, can become infected.

Pekelharing and Winkler first called attention to the presence of diplococci in the blood, to which they attributed the disease, but their culture-experiments must be looked upon as far from conclusive. Many other observers have experimented with the same bacteria, but cultivation and inoculation, though followed sometimes by a certain amount of success, in that symptoms of neuritis (as in several of the experiments of Hunter with rabbits) followed the inoculation, have not by any means proved the causation of the disease. Two points may be mentioned in this connection: the first that Ellis, in working at beriberi at Singapore, found an apparently identical diplococcus frequently present in the blood of persons to all intents healthy; and the second that von Tuzelmann produced, by cultivation on agar-agar from a kind of fungous growth found on the woodwork of a hospital-ward in which cases of beriberi had occurred, growths of organisms also apparently identical with the same diplococcus. These points may perhaps tend to indicate that it may yet be found that the bacterium in question may exist innocuous in the blood, though capable of manufacturing the poison in suitable environment outside the body.

PATHOLOGY AND MORBID ANATOMY.—The pathology of beriberi is that of a multiple peripheral neuritis, the paralytic symptoms and aberrations of sensation being caused by affection of the motor and sensory nerves, the oedema and effusions of fluid by affection of nerves of vaso-motor function. If the disease does not last long (and the nerve-degeneration seems capable of rapid repair); the only pathological condition is the neuritis, but if the paralysis lasts any considerable time, as occasionally happens, the muscles affected become shrunken and atrophied. The præcordial oppression and vomiting that usher in alarming symptoms, the oedema of the lungs, the paralysis of the diaphragm, and the paralysis and dilatation of the heart, are all caused by neuritis of supplying nerves. The cause of death is not always the same; paralysis of the diaphragm has been put forward as a frequent cause of death, but a patient will occasionally lie for days with purely thoracic breathing, and ultimately recover; pericardial effusion no doubt sometimes causes death, but only rarely in the experience of the writer. Death most frequently results from paralysis and dilatation of the heart, helped often by pulmonary oedema; it may also occur from pulmonary oedema alone, the heart-muscle remaining unaffected. The post-mortem appearances vary with the cause of death. Oedema and effusion into serous cavities may be present in varying degree; three ounces or more of fluid is nearly always found in the pericardium. In death from uncomplicated pulmonary oedema the lungs are found gorged with blood and frothy fluid, which pours out when the organ is incised; in such a case the heart may be found with ventricles in systole, but containing fluid blood, the large veins and auricles being distended; ecchymotic spots are sometimes found in these cases under the visceral pericardium. In death from paralysis of the heart that organ is found dilated, often enormously, with ventricles in diastole, and all cavities and great vessels full of blood and clot; the lungs are congested and may be somewhat oedematous; there is generally pericardial effusion to the amount of three or four ounces. Neuritic degeneration can be demonstrated in the affected nerves,

most readily in the peroneal and tibial, but it has also been found among others in the vagi, phrenic, and renal nerves, and those of the cardiac plexus. If the muscles of the legs or arms are much atrophied, the fibres will be found to have lost their striation, and the teased specimen will look like a collection of fine fibrils with homogeneous spaces between them.

SYMPTOMS AND DIAGNOSIS.—The disease may present symptoms of oedema, or muscular paralysis, or both. These different groups of symptoms are best described separately, it being borne in mind that varying degrees of both may, and usually do, occur simultaneously, though one kind generally predominates, and that there is no true division into *wet* and *dry* varieties of beriberi. The oedema commences with slight swelling over the lower part of the shin, increasing and spreading upwards over legs, thighs, trunk, upper extremities, and face, so that, when the disease is, so to speak, fully developed, the patient lies in a bloated, helpless condition. There may also be ascites, hydrothorax, or hydropericardium. The urine in these cases is scanty, high-coloured, and of high specific gravity; it is never albuminous. These symptoms are generally accompanied by more or less difficulty in standing or walking, loss of patellar reflex, and tenderness on deep pressure over the gastrocnemii and adductors of thigh. When the *paralysis* predominates, there is first some difficulty in walking, and afterwards absolute inability to walk or stand; if the patient be supported, and told to try and walk, the leg and foot are lifted by the thigh-muscles, and hang loosely from the knee, the foot being dropped from the ankle; there is loss of patellar reflex from the outset, and tenderness on squeezing the gastrocnemii and inner thigh-muscles; there is often a feeling of numbness and anaesthesia of the skin over the front and outer part of the leg and dorsum of the foot. Hyperaesthesia of the skin is occasionally met with. If the arms are affected there is wrist-drop, and often anaesthesia and numbness of the skin over the back of the forearms; sometimes anaesthesia is found around the mouth, and there may be paralysis of the lip-muscles, or occasionally of the muscles of the larynx, leading to loss of voice. There is never any paralysis of bladder or rectum, and the cremasteric and abdominal reflexes are, so far as the writer knows, never lost. These symptoms, as above mentioned, may be accompanied by oedema in varying degree. Functional cardiac murmurs are said to be frequently heard, and Manson calls attention to an alteration in the heart-rhythm. If the disease last long, the paralysed muscles become wasted, and recovery is slow; but often under appropriate treatment both kinds of symptoms subside rapidly. At any time in the course of the disease alarming symptoms may set in, and a patient who does not seem seriously ill may die in a few hours. Dangerous symptoms are generally ushered in by a feeling of præcordial oppression, and the vomiting of frothy fluid; then restlessness and dyspnoea set in, with rapid action of the heart, distended jugular veins, and terrible distress generally. In death from asphyxia due to pulmonary oedema, the distress is worse even than in death from cardiac paralysis. The dyspnoea is worse, the jugular veins are more distended, the pulsation in the neck is more marked, the face more livid, and the pulse hard; in death from cardiac paralysis the restlessness is

the same, but there is breathlessness rather than dyspnoea, the pulse is rapid but soft, the temperature falls, and the heart, becoming more and more dilated, as evidenced by percussion, gradually fails. Death from pulmonary oedema alone is infrequent, cardiac paralysis and dilatation being usually present to a greater or less degree, and adding to the danger. Cardiac murmurs are frequently heard, generally systolic; and præcordial pulsation is marked. The presence of pulmonary oedema is shown by impaired resonance, and crepitation, especially over back of chest. The diagnosis of beriberi, when it occurs in epidemic form, is not difficult, but it must be remembered that the symptoms are indistinguishable from those of peripheral neuritis produced by some metallic poisons, and poisoning by some of these may occur in epidemic fashion; epidemics of beriberi are, however, generally met with in tropical or sub-tropical countries. Sporadic cases are probably never met with except in the last-named localities, and here the history will help in distinguishing them from cases of neuritis caused by alcohol. *See* NEURITIS, MULTIPLE.

PROGNOSIS.—The prognosis in beriberi, in consequence of the liability to dangerous symptoms, must always be grave. Unfavourable signs are præcordial pain and pulsation, vomiting, restlessness, evidence of cardiac dilatation (as shown by percussion, and, as pointed out by Manson, by alteration of the cardiac rhythm), increasing rapidity of pulse, and a fall of temperature.

TREATMENT.—The medicinal treatment of the disease consists in the treatment of symptoms. The oedema is best dealt with by free purgation with elaterin and the administration of diuretics, of which scoparium is probably the best. Pineapple-juice has been found of service in increasing the flow of urine, and this fruit may with advantage be given as an adjunct to treatment by drugs. For the paralytic symptoms arsenic and strychnine are probably the best remedies; later, if the muscles are wasted, galvanism may be used. As regards the dangerous symptoms, if the pulse is hard and the distress great, with physical signs indicative of lung-oedema, great relief, and in uncomplicated cases often cure, is given by nitroglycerin in doses of two to four drops of the one per cent. solution dropped upon the patient's tongue, every hour at first, and afterwards at longer intervals as relief is given. The drug may be assisted by blisters to the back of the chest. A case is hopeless in proportion to the degree of paralysis and dilatation of the heart present; in these cases nitroglycerin gives too often only temporary relief. Probably the best remedies when the heart is dilated, the pulse rapid but soft, and the temperature falling, are digitalis, or injections of strychnine, with the use of artificial warmth externally. Pericardial effusion, if endangering life, should be dealt with by aspiration. The most important measure in treatment is the removal of patients from the place where they have contracted the disease, and this removal alone is often conducive to speedy recovery, even sometimes when the advent of alarming symptoms may seem imminent. The place to which removal is made should of course be one of which the position and hygienic conditions are the reverse of those mentioned as favourable to the spread of the disease; a sea-voyage often acts beneficially. As regards diet, it should be good; a great deal has

been said as to the necessity for a rather large proportion of nitrogenous food, and in the case of natives this is best effected by the substitution of beans or wheaten flour for a portion of the rice which is usually the chief article of diet. In the case of epidemics on ships, in schools, gaols, and similar institutions, patients should be removed if possible; but in any case cleaning and disinfection should be practised as though a contagious disease were being dealt with.

BILE, Disorders of.—The bile is an excretory fluid through which are removed not only products of blood-destruction such as the bile-pigments, but also other effete products filtered off by the liver from the blood arriving from the digestive tract—products the presence of which in the general system would be attended with ill effects. Furthermore, in relation to the process of digestion it materially aids the assimilation of fats from the intestine and has valuable laxative properties; but an even more important function is the one recently discovered (1897) by T. R. FRASER, namely that it has a remarkable power of antagonising and rendering inert powerful organic poisons, such as that of snake-bite. There are many poisonous products generated in the intestine, capable, if absorbed, of producing ill effects. The symptoms so commonly ascribed to 'sluggish liver' or 'want of bile' may be due, in part at least, to the absence of a sufficient amount of healthy bile and to the consequent absorption of products that would otherwise have been rendered inert by it. The undoubted value of cholagogue substances—'stimulants of bile-secretion'—so long employed on empirical grounds alone, may thus obtain a satisfactory explanation.

The amount of bile secreted daily varies greatly under the influence of many different factors. The chief of these factors in health is the taking of food. The flow of bile increases when food is taken, and falls when food is withheld. Throughout the 24 hours its flow is irregular: being highest in the middle of the day (12 to 4), and lowest in the early hours of the morning. The flow of bile is greatly influenced by the amount of fluid taken; it is the flushing of the biliary system with water which serves to explain the remarkably beneficial action of so many Mineral Waters. The influence of drugs in promoting the flow of bile is probably overrated. No drug is so powerful in this respect as the bile or the bile-salts. Among the various drugs accredited as cholagogues are:—Alkalies, chloride of sodium, sulphate of sodium, sulphate of potassium, phosphate of sodium, mercuric chloride, ipecacuanha, colchicum, jalap, aloes, colocynth, rhubarb, benzoate of sodium, and salicylate of sodium. The only one whose power in promoting an increased flow of bile has been fully ascertained is salicylate of sodium.

No factor is more important in producing so-called 'bilious' disorders than *diminished secretion of bile*. The trouble it occasions arises not so much from any diminished output of the bile-pigments and bile-salts as from (1) the retarded flow of bile, giving opportunity for the absorption of its constituents and for disturbance of the liver itself; and (2) the lack of bile in the intestine, permitting the absorption of injurious products which might otherwise have been rendered innocuous. This diminished secretion may be the outcome of defective action on the part of the liver itself and a consequently defective *vis a tergo*; such is probably its character in all febrile conditions. But another and, in the opinion of the writer, more potent factor is any increase of resistance to its flow (at all times under very low pressure) along the bile-passages. This increase of resistance may arise from two causes: from increased secretion of mucus from the bile-passages and corresponding increased viscosity of bile, or from sluggish muscular action of the walls of the bile-ducts. The latter is of doubtful importance; the former is the condition that is generally present in cases of 'biliousness.'

This increased viscosity is largely due to the action on the lining mucous membrane of a morbid or altered bile. One of the chief functions of the liver is not merely to excrete, but to destroy various products carried to it from the digestive tract. These products are formed in the stomach and intestine and carried to the liver in the portal blood. The liver partly destroys and partly excretes them. If the character of those excreted is such as to irritate the bile-passages along which they pass, the result is an increase of mucus, an increased viscosity of bile, and, as a secondary consequence, a retardation of its flow and a diminution in its quantity.

A large number of substances introduced into the blood may also in this way be *excreted* by the liver, e.g. iodide of potassium, cane- and grape-sugar, sulphate of copper, oil of turpentine, iron, lead, arsenic, silver, chlorate of potassium, salicylate of sodium, toluylenediamin—in some cases very quickly. Thus in the case of the last-named drug the writer detected it in the bile within half an hour, and in 3 to 4 hours it was present in quite appreciable quantity.

On the other hand other drugs are not excreted but *destroyed* by the liver, e.g. atropine, muscarine, strychnine, antipyrine, and quinine. Interference with the destroying function of the liver causes disorder in two ways. (1) By permitting products to pass through the liver into the general circulation, it is probably accountable for certain of the more common symptoms usually ascribed to 'disordered liver'—giddiness, cloudiness of intellect, drowsiness, irritability, and depression (*see* LIVER, Functional Disorders of). (2) By permitting irritant products to pass into the bile-channels, it is a common cause of biliousness. No harm would happen did the liver pour its secretion into the intestine through a wide channel. Unfortunately it happens that the bile with any irritant products it contains has to pass through a whole system of narrow bile-channels lined with secreting cells. The effect of the irritation is to excite an increase of mucus. If it be very intense the mucus secreted may be so great in quantity and so viscid in consistency that the flow of bile is arrested altogether and jaundice results, just as intense as if the flow of bile had been stopped by a ligature applied around the main duct.

Fortunately such poisons are rare and they are only met with as the cause of the more severe forms of jaundice (*see* JAUNDICE). But there can be no doubt that many products of abnormal digestion do possess certain irritant qualities, the excretion of which may occasion a certain retardation in the flow of bile. This is one of the conditions underlying the ailments known as 'biliousness,' or 'torpor of the liver.'

As above shown, in most cases the primary fault leading to disorder of the bile, whether in quantity or quality, arises, not within the liver, but outside it, in the stomach or intestine. The only fault the liver is responsible for is that it has excreted products which have proved more or less injurious to its bile-ducts. *See* GALL-BLADDER and BILE-DUCTS.

WILLIAM HUNTER.

BILHARZIA.—The name given to a genus of flukes, discovered by Dr. Bilharz, of Cairo. *See* ENTOZOA.

BILIARY CALCULUS.—*See* CONCRETIONS; and GALL-STONES.

BILIARY FISTULA.—There are two kinds of biliary fistula: one, in which a communication exists between the gall-bladder and the surface of the body; the other, in which there is a communication between the gall-bladder and other internal organs. Both are rare as the result of disease; but they are not infrequently produced by operation in cases of obstructed bile-duct undertaken in order to divert the flow of bile either outwards or into the intestine.

There are a few cases on record in which a tumour has formed in the neighbourhood of the gall-bladder, and finally has opened spontaneously and discharged a quantity of pus, bile, and gall-stones. Suppuration of the gall-bladder, associated with the presence of gall-stones, is the common cause of these fistulae.

In the second kind of biliary fistula the gall-bladder may communicate with the duodenum or colon; or even with an abscess of the liver; with the portal vein, or with some part of the urinary tract. Gall-stones are in nearly every case the cause of the fistulous opening. *See* GALL-STONES.

WILLIAM HUNTER.

BILIOUS.—This term is used popularly to designate a particular temperament and to describe a peculiar sallow appearance of the skin, suggestive of slight jaundice. When vomit is bile-stained, it is also called 'bilious.' One of the most frequent applications of the term is to certain so-called *bilious attacks* or *biliousness*, which, however, are commonly attacks of migraine (*see* MEGRIM), or are due to digestive disturbances (*see* BILE, Disorders of). In the latter case, the most prominent symptoms are anorexia, furred tongue, a bitter taste, sickness, constipation, and headache, with a feeling of marked depression and general malaise. Such attacks are most effectually prevented and treated by careful regulation of diet. Salicylate of bismuth, cholagogue aperients, and saline effluents may be given, but alcoholic stimulants should be avoided.

BIRTH-PALSIES.—*See* CEREBRAL DIPLEGIA.

BITTER ALMONDS, Poisoning by.—*See* PRUSSIC ACID, Poisoning by.

BLACK VOMIT.—Vomited matters may be more or less black in different diseases, but the term *black vomit* is generally restricted to the vomit occurring in the severest forms of yellow fever (see **YELLOW FEVER**). The rejected matters are acid in reaction, and a sediment is deposited consisting of disintegrated blood-corpuscles and glandular epithelium, granules of pigment, and bacteria. The black colour is due to the altered blood. See **HEMATEMESIS**.

BLACKWATER FEVER.—**SYN.** : Hæmoglobinuric Fever; Bilious Hæmoglobinuric Fever; Fr. *Fèvre Bileuse Hémoglobinurique*; Ger. *Schwarzwasser-Fieber*.

DEFINITION.—An acute infective disease running an indefinite course, characterised by rapid hæmolytic, and giving rise clinically to pyrexia, hæmoglobinuria, and icterus.

ETIOLOGY.—The disease was first described by French surgeons in Madagascar in 1850. Since then it has been observed to occur throughout tropical Africa, in some of the southern states of America, in the West Indies, in Assam and other parts of India, and in Sicily and Sardinia.

Blackwater Fever, at the present time, vies with malignant malarial fever in the amount of invaliding and mortality it causes among Europeans in Tropical Africa. The specific agent is, as yet, undetermined; by some it is believed to be a purely malarial affection, because it occurs only in malarious regions, because the malarial parasite is sometimes found, and because it is prone to attack those who have previously suffered from malarial fever. On the other hand, the seasonal prevalence of the two diseases frequently differs, the malarial parasite is not usually found in the blood, and new arrivals occasionally contract the disease.

Sambon has suggested that the disease is closely related to Texas fever of cattle, and Koch has advanced the view that it is nothing more than quinine-poisoning, although it has been shown that individuals who have never taken quinine suffer from the disease. It is probable that it is caused either by an organism closely allied to, yet distinct from, any of the known species of malarial parasite, by some unknown conditions which modify the ordinary malarial parasite. Chills predispose to attacks. It is very prone to relapse, and the disease may occur for the first time some months after the patient has left the endemic region and returned to Europe.

SYMPTOMS.—The attack may be preceded by fever and malaise, but it is usually abrupt and ushered in by a rigor, or a succession of rigors, the temperature reaching 103° to 105° F. There is pain in the head, back, loins, and abdomen. Bilious vomiting sets in early and persists. Micturition is frequently painful. Within a few hours the skin and sclerotics assume a saffron-yellow tint. In four to six hours sweating occurs and the temperature falls. The rigor may return the next day or within a few hours and be repeated for five or six days. In mild cases there may be only a single rigor. In severe cases, with each succeeding rigor, the symptoms become aggravated. The patient becomes restless, breathless, and complains of thirst, and the vomiting is incessant. In such cases death may supervene as early as the second day, or as late as the second or third week. When death occurs early it appears to be due to the rapid hæmolytic, which may give rise to symptoms like those of hæmorrhage. When it occurs

late in the course of the illness, it is usually due to syncope, suppression of urine, or intercurrent disease. Death from syncope may occur at any time during the attack.

On examination of the blood the plasma is coloured yellow from the dissolved hæmoglobin; the red corpuscles are misshapen and vacuolated; and shadow-corpuscles are present. There is a marked and rapid diminution in the number of the red corpuscles, which may fall to one and a half or one million per cub. mm. in two or three days. The hæmoglobin may also fall to 20 per cent. of the normal amount. There is a mononuclear leucocytosis, and pigmented leucocytes are generally present. The malarial parasite is often absent.

The urine varies in colour from cherry-red to black. On shaking, the froth is pinkish. On standing a copious deposit forms, of a greyish-brown colour, consisting of corpuscular debris, hyaline and blood-casts, and a few red corpuscles. On heating a dense coagulum of globulin forms. Spectroscopic examination reveals the absorption-bands characteristic of hæmoglobin or occasionally of methæmoglobin (see **SPECTROSCOPE IN MEDICINE**). As the patient improves the urine clears rapidly and the globulin disappears. The urine should be examined daily during convalescence, as nephritis occasionally supervenes. The liver and spleen are usually enlarged and tender.

MORBID ANATOMY.—The fluid in the serous cavities is of a bright yellow colour. The liver is enlarged and yellow in colour, and the gall-bladder is usually distended. The spleen is enlarged and its parenchyma soft. The kidneys are congested, and on microscopical examination the convoluted tubules are seen to be filled with hæmoglobin-casts. If pyrexia has been a marked feature of the case, cloudy swelling of the various organs will be present.

DIAGNOSIS.—Blackwater fever has to be distinguished from Bilious Remittent Malarial Fever and from Yellow Fever. In the former there is no hæmoglobinuria, but the urine contains bile and little, if any, albumen. Rigors are not a marked feature, and the temperature is remittent in type. The malarial parasite is invariably present in the blood. The urine on shaking presents a yellow, not a pink, froth. In yellow fever icterus and hæmaturia are late symptoms, and true hæmoglobinuria does not occur. The fever is sthenic in character at the onset, the pulse is slow, and a period of apyrexia precedes the asthenic stage of the disease.

PROGNOSIS.—The mortality varies in different years and in different places. In recent years it has been higher in Central Africa than in West Africa. It fluctuates between 12 and 60 per cent. Mild cases usually recover rapidly, and sometimes apparently hopeless cases pull through. A relapse is often less severe than the primary attack.

TREATMENT.—No specific treatment for blackwater fever has yet been discovered. If the malarial parasite be found, quinine should be administered cautiously, bearing in mind that the drug occasionally aggravates the hæmoglobinuria. A favourite remedy in West Africa, at the present time, is salicylate of sodium. A preliminary purgative of five grains of calomel should be given. Copious draughts of barley-water or some other demulcent drink, containing some mild diuretic, such as citrate of potassium, should be administered. Symptoms of collapse must be promptly treated with hypodermic injections of strychnine or ether. The

usual remedies for vomiting may be tried ; as a rule, however, they do little good. Nourishment must be given if necessary *per rectum*, but it is advisable to persevere with fluids by the mouth, even if they be vomited. In extreme cases, normal saline solution may be injected subcutaneously or intravenously. During convalescence arsenic and other blood-restoratives are indicated. The patient should be strongly advised to leave the endemic area on account of the continued liability to relapses.

DAVID C. REES.

BLADDER, Diseases of.—SYNON.: Fr. *Maladies de la Vessie* ; Ger. *Blasenkrankheiten*.

The bladder may be the seat of the following morbid conditions:—Inflammation, infective (including abscess and ulceration) or non-infective ; Neuralgia ; Atrophy or Hypertrophy ; Mechanical Distension, with chronic engorgement and retention of urine, commonly, but erroneously, termed 'Paralysis' ; Sacculations ; Displacements, such as hernia in the male, or, very rarely, inversion and protrusion in the female ; Tumours or Growths of various kinds, from simple Mucous Polypi to Sarcoma, and Carcinoma ; Cysts ; and Vesico-vaginal or Vesico-intestinal Fistula. The bladder may also be the subject of true paralysis, partial or complete, as the result of injury to, or disease of, the brain or spinal cord.

1. Inflammation of the Bladder or Cystitis may be divided into two classes: (1) *Infective Cystitis*. (2) *Non-infective Cystitis*.

(1) **Infective Cystitis.**—This class includes by far the larger proportion of cases. The inflammation is caused by the presence of some pathogenic micro-organism which infects the urine or the tissues of the bladder, separately or both at the same time. The organism may be introduced into the bladder from *without*, by the passage of a septic instrument, by an injury, or by the extension of gonorrhœa. On the other hand the infection may arise from *within*, being part of a general infection, as in tuberculosis, typhoid fever, or diphtheria ; or as a local infection from a neighbouring organ, as in disease of the rectum, uterus, and alimentary canal. Infective cystitis may be conveniently subdivided into *Acute* and *Chronic* varieties.

A. Acute Infective Cystitis is due to infection from without. The disease is usually ushered in, a few hours after infection, by discomfort in the region of the perinæum and bladder, chilly feelings in the back—in severe cases even rigors—and general malaise. These symptoms quickly give place to frequent and painful micturition, small quantities of urine being voided with urgency and often with straining. There is constant aching and feeling of weight in the perinæum and rectum, with sometimes slight suprapubic pain and tenderness. The temperature is slightly raised, the rise corresponding to the degree of local inflammation. The urine is slightly acid, or alkaline in reaction, cloudy from the presence of mucus, pus, epithelial cells, micro-organisms, and occasionally, in severe cases, blood-corpuscles. Among the organisms commonly met with are the *Bacillus coli communis*, the *Gonococcus*, and various pyogenic cocci. The infective process is confined to the mucous membrane, involving either part or the whole of the surface, which is swollen, congested, and, in severe cases, dotted with small hæmorrhages.

The disease generally subsides in the course of a week or so, though its duration depends to a great extent on the amount of septic infection to which the bladder has been subjected.

TREATMENT.—The *general* treatment consists of rest in the recumbent position, of very hot bidets or hip baths, and hot applications in the form of poultices, fomentations or hot-water-bottles to the lower part of the abdomen and perinæum. To relieve distressing symptoms opium or morphine administered by the mouth, or better by suppositories or hypodermic injections, may be required, but as a rule the preparations of belladonna and hyoscyamus are alone necessary. The diet should be simple ; all alcoholic stimulants should be forbidden and the patient should drink freely of diluents. The *special* treatment is directed to the elimination of the micro-organisms, while at the same time great care should be exercised to prevent reinfection. For this purpose some antiseptic preparation is injected into the bladder. Among those employed may be mentioned solutions of boric acid (2 to 4 per cent.), carbolic acid (.5 to 1.0 per cent.), resorcin 1 per cent., nitrate of silver (1 in 1,500 to 1 in 2,000), perchloride of mercury (1 in 10,000 or weaker), normal salt-solution, and iodoform-emulsion. The internal administration of salicylate of sodium, boric acid, benzoic acid, salol, or urotropine is generally recommended, though perhaps not so immediately effective.

B. Chronic Infective Cystitis arises (1) from the introduction of micro-organisms from without into a bladder already subject to abnormal conditions, such as retention of urine, stone, stricture, tumours, and the presence of morbid urine ; and (2) from infection of the bladder by micro-organisms conveyed from some other part of the body. It not uncommonly commences with all the symptoms of an acute attack, and when these have subsided the patient may have little or no inconvenience for long periods, the only objective symptom being the cloudy condition of the urine. In other cases the disease comes on quite insidiously, the severity of the symptoms gradually increasing. In a few instances the symptoms are pronounced from the beginning and continue throughout the course of the disease. In all forms the patient is liable to acute exacerbations. The symptoms are then very severe, consisting of great pain and frequency of micturition, much straining, and pain in the abdominal and lumbar regions. Rigors are frequent, the temperature remains high throughout the attack, and is associated with grave constitutional disturbance. The urine is thick, offensive, and alkaline. It contains much ropy muco-pus, vesical epithelium, often blood, organisms of many kinds, and various crystals, due to the decomposition of the urine. The structural alteration of the bladder is much more marked and involves all the coats. The mucous membrane is of a greyish appearance, is covered with muco-pus, is thickened and congested, and contains hæmorrhagic extravasations. Exfoliation of the epithelium in large masses may occur, thus giving rise to ulceration, while infection of the deeper layers without erosion may result in *abscess*. The muscular coat is hypertrophied, especially the superficial interlacing fibres, causing the roughened and rugose condition so often noted in bladders long affected with this disease. The blood-vessels of the mucous membrane are dilated, especially towards the neck of the bladder ; these may rupture and give rise to severe hæmorrhage.

Cases of chronic infective cystitis do not often recover completely, unless it is possible to cure the co-existing abnormalities of the bladder.

TREATMENT.—The same general treatment should be adopted for chronic as for acute cystitis, especially when exacerbations occur, but in addition the abnormal condition of the bladder and the sources of infection from neighbouring parts should be removed if possible. Thus in cases of retention the urine should be drawn off by catheter at regular intervals. Stones must be removed, strictures dilated, and specific treatment adopted in tuberculosis. The septic condition of the bladder should be dealt with by injections as already indicated. To the list of internal remedies previously mentioned should be added the infusions and decoctions of *Triticum repens*, *Uva ursi*, *Alchemilla arvensis*, *Buchu*, and *Pereira*, together with the salts of sodium and potassium, as well as the natural mineral waters of Evian, Vichy, and Contrexéville.

(2) **Non-infective Cystitis.**—This form of inflammation is caused (1) by the toxic effect of drugs, as cantharides or turpentine; (2) by the introduction of strong chemical irritants into the bladder, as occurs when instruments that have been disinfected with strong solutions of carbolic acid are passed; (3) by an aseptic injury, as may be caused by some sterile instrument, or by some crystalline deposits from the urine; and (4), although this is questioned, by the presence of residual urine.

The symptoms are similar to those of acute infective cystitis. The urine is generally acid, and cloudy with mucus and epithelium; but it contains no pus or micro-organism. Blood is generally present in considerable quantities when the cystitis is induced by a toxic agent. The attack is transient, subsiding in the course of a few hours after the removal of the exciting cause.

2. **Neuralgia.**—It is impossible to deny that the bladder may be subject, like other parts of the body, to symptoms which are described as neuralgia, although the occurrence is an extremely rare one. All the writers can say is, that they have occasionally met with cases in which they were unable to account, by the existence of any lesion, for pain and frequency in micturition, or for difficulty in performing that act, and where these symptoms have been more or less periodic in their appearance. In such instances quinine or arsenic was given, and occasionally great relief followed a few doses; more frequently this has not been the case. It is invariably necessary to investigate the general health, as well as the habits and diet of the patient. This, perhaps, may be the place for stating that in all chronic and slight deviations from natural and healthy function in the urinary organs, it is necessary to inquire into the state of the digestive organs, and, if possible, to correct by diet, and by medicine when necessary, any imperfect action on their part. Constipation alone, when habitual, may produce considerable irritability of the bladder, a slight affection of the organ already existing; so also may the unnecessary use of purgatives. A daily action of the bowels, and a healthy condition of the digestion, should be ensured as far as possible in all patients complaining of frequent, difficult, or uneasy micturition; and many such may be completely cured of so-called urinary affections by strict attention to these matters. For such patients, the natural aperient waters of Germany and Hungary are of inestimable benefit.

3. **Hypertrophy and Atrophy.**—Where obstruction to the outflow of urine exists, as from stricture of the urethra, enlarged prostate, or tumours, the muscular walls of the bladder become the seat of compensating hypertrophy. Thickening of the muscular walls may also result from long-standing inflammation. Such changes in the interlacing muscular fibres are readily followed by **Sacculation** due to protrusion of the lining membrane between the bands so produced; or the trabeculae may obstruct the orifice of the ureters, causing dilatation of those passages. In some cases the muscular coat undergoes colloid or fatty degeneration. In the former condition the bladder loses its flexibility and elasticity, and in the latter is so weakened that perforation may easily occur. On the other hand, when no increased muscular force avails to empty the bladder, as may occur when the prostate is much enlarged, the bladder becomes gradually distended, its coats become expanded, thinned, and weakened, and a certain degree of **Atrophy** takes place. The power of the organ to expel urine is lost or diminished; and a catheter is the only means of relief. But atrophy and loss of power, needing the habitual use of the catheter, may also occur from complete or partial loss of nervous influence over the bladder, as in those who are the subjects of paralytic states commencing in the spinal cord or brain. Indeed the difficulty in micturition may be the first recognised sign of organic disease of the nervous system.

4. **Tumours.**—Tumours of the bladder are more frequently met with in men than in women. In order of frequency papilloma ranks first, carcinoma second. The following kinds may be enumerated.

(1) **Mucous Polypus.**—Mucous polypus is not to be confounded with prostatic outgrowths of the same form, these being inadmissible in any scheme comprising vesical tumours. It resembles polypus of the nasal cavity, but is more compact and solid in structure, and is chiefly composed of myxomatous tissue. Hitherto this product has been found in young children only.

(2) **Papillomatous Tumours.**—These growths consist of masses of soft papillae (*see* TUMOURS), and were formerly termed 'villous,' to which it was not unusual to add the word 'cancer,' in many cases erroneously, yet in some not an altogether inappropriate term, as carcinoma is liable to develop in the base of a papilloma. These growths, which may be pedunculated or sessile, single or multiple, frequently spring from the fundus of the bladder. When fully developed they give rise to repeated attacks of hæmorrhage, which in time become continuous and copious, thus terminating life. Painless hæmaturia is the characteristic symptom, though in certain cases pain in the lumbar and renal regions is noted from the first, due no doubt to obstruction of the ureters by the growth. In addition there is sometimes increased frequency of micturition, a 'tickling' sensation along the urethra, and occasionally sudden stoppage of the flow of urine. Moreover, on careful enquiry it may be ascertained that, while at the commencement of the act of micturition the urine is clear or almost bloodless, at the end of the act bright florid blood is mixed with the stream, or appears alone at the close. The hæmorrhage arising from papillomata is not infrequently attributed to a renal origin, but the above mentioned symptoms coupled with the fact that microscopical examination of the urine will sooner or later (especially if the

bladder is washed out with sterile water and the débris collected) detect characteristic specimens of growth, and establish the diagnosis beyond a doubt.

TREATMENT.—Papilloma, especially the sessile variety, even when freely removed by operation, frequently recurs. This fact led the writers to adopt the practice of injecting into the bladder a solution of nitrate of silver, with the idea of checking the hæmorrhage and repressing the growth. During the last ten years fourteen undoubted cases have been subjected to this treatment with a result that all have been relieved of symptoms for long periods. The treatment is commenced by injecting daily into the bladder a solution of half a grain of nitrate of silver in four ounces of sterile water (99° F.) acidulated with a small quantity of free nitric acid. The solution is kept in the bladder half a minute and is then allowed to run out. The injections are continued without intermission for four, five, or six months, the strength being gradually increased until a solution of two grains of nitrate of silver to four ounces of water is used. The treatment is then relaxed and the patient not uncommonly remains free from symptoms for a considerable time; though it should be again resorted to whenever blood reappears at short intervals or in large quantities.

(3) *Myomata*.—These are not common, and are unaccompanied by any characteristic signs of their presence.

(4) *Fibromata*.—Both these and the preceding kind of tumour involve the deep structures of the organ, and cannot generally be removed entirely by operative procedures unless they are detected in an early state.

(5) *Carcinomata*.—Primary carcinoma of the bladder is rare, if those forms developing in the base of papillomata be excluded. It usually appears after middle life. Epithelioma is the commonest form, though cases of scirrhus have been recorded. In the early stages these growths may give rise to no marked symptoms, and the disease has probably invaded the organ to a considerable extent and even ulcerated, before the recognised symptoms of pain, frequency of micturition, and hæmorrhage occur.

(6) *Sarcomata*.—These are most commonly met with in children.

The diagnosis of malignant disease of the bladder in its early stages is often attended with much difficulty. At a later period examination of the rectum furnishes valuable information. Scirrhus cancer is very hard, irregular in form, and thus unlike any simple prostatic enlargement occurring in elderly men. Sarcomata are rounded in form, more elastic to the touch than 'prostatic enlargement,' and far more rapid in their rate of increase. Epitheliomata, slow and restricted in growth, may exist some years before presenting a tumour sufficiently dense to be recognised by palpation or sounding. In all forms of malignant disease pain is the most constant symptom, and some hæmorrhage is liable to appear, increasing at a later date, thus contrasting with papilloma, which latter is rarely recognisable through the rectum, commences with hæmorrhage, and is not painful. The progress of epithelioma is slow, and without any very distinctive characters. Microscopical examination of the urine for shreds of tissue and cells furnishes valuable information, but the principal aid in forming an early diagnosis is the judicious use of the cystoscope, which not only demonstrates the

kind of tumour present, but also indicates its size and position. *See* BLADDER, Examination of.

If a diagnosis is made in the earliest stages it may be possible to extirpate the disease. But if the growth largely involves the organ, operation to remove it entirely is almost impossible. Rapid recurrence follows although large masses have been removed and an apparently empty cavity has been left as the result of the procedure. The palliative treatment for all patients thus affected consists in the avoidance of habits, occupations, and forms of exercise found, by the experience of each individual case, to produce serious increase of hæmorrhage. Instrumentation, whenever necessary, should be undertaken with the strictest antiseptic precautions, for the occurrence of infective cystitis adds very greatly to the suffering and distress of the patient. Lastly, all means should be adopted to alleviate suffering by the free use of morphine.

5. Cysts.—They are exceedingly rare, and when they occur usually occupy the posterior wall of the bladder. They may be derived either from remnants of embryonic structures, or produced by the dilatation of some existing canal, or may be of parasitic origin (hydatid). *See* ENTOZOA.

HENRY THOMPSON.

H. T. HERRING.

BLADDER, Examination of.—The following methods are now available for the systematic examination of the bladder:—

1. *Examination by metal instruments.*—The sound is used almost entirely for the detection of stone. It may, however, in rare cases fail even when the stone is of considerable size. In such cases failure is usually the result of the stone being more or less hidden behind a greatly enlarged prostate. The sound, even when its beak is turned downwards, may not hit the stone. Calculi also may be concealed in hernial pouches of the mucous membrane, communicating with the general cavity of the bladder by a small aperture. A mistake frequently made in sounding for stone is to depress the handle of the instrument between the thighs of the patient, and so to keep it during the examination. When once the beak has passed over the prostate and is safely in the bladder, the handle should be somewhat raised, so that the beak is depressed behind the prostate, the most usual position for vesical stone. The sound also detects any roughness or trabeculation of the walls of the bladder. In conjunction with a finger in the rectum the limits of an enlarged prostate may be determined, and the condition of the lower portion and trigonal area of the bladder ascertained.

By the use of a metal evacuating cannula and wash-bottle, such as are used in the operation of litholapaxy, the presence of small stones may often be determined. The calculus is sucked against the eye of the catheter, the resulting click being distinctly audible at some distance from the patient.

2. *Bimanual Examination.*—Rectal or vaginal examination, combined with pressure upon the lower part of the abdomen, is often of great service. In a spare individual the examining hands can almost be made to meet, and the condition of the bladder-walls, the prostate, and the seminal vesicles can be to a certain extent ascertained. With a full-sized bougie or sound in the urethra the condition can be determined still better.

3. *Exploratory operations* are seldom necessary,

or their place is taken by the cystoscope. Still, when the cystoscope fails, an operation may be necessary to determine the condition present. In such cases the bladder may be opened for digital examination either (1) by a perineal section, or (2) by the suprapubic method. For exploratory purposes the latter operation is to be preferred. Great assistance is afforded by the use of caissons or porcelain specula passed through the suprapubic wound and moved over the internal surface of the bladder. A brilliant light can be thrown upon the mucous membrane from an electric lamp worn upon the brow of the operator. The surface can be dried by means of small sponges or cotton swabs in sponge-holders, and the condition of the interior accurately discovered. It is generally advisable to

The catheter-cystoscope is simply an ordinary cystoscope enclosed in an outside metal tube. This tube or metal catheter is first introduced with an obturator in position. The obturator is withdrawn, the bladder washed out, and the cystoscope proper introduced in the place of the obturator. This device obviates the necessity of introducing an instrument more than once in the performance of cystoscopy.

The irrigation-cystoscope can be understood from a glance at the accompanying figure (fig. 2). By its aid a constant stream of liquid can be passed through the bladder, the viscus being under observation the while.

Lastly must be mentioned the highest development of the instrument at present attained—namely, the

FIG. 1.—Cystoscope

consist upon general anæsthesia for careful bladder-examinations. Local anæsthesia is sufficient to abolish pain, but great inconvenience may be and often is experienced from the spasmodic contraction of the abdominal and perineal muscles, often rendering it difficult to use sound or catheter.

4. *The Cystoscope*.—Many forms of this instrument are now in use. In the instrument preferred by the writer (fig. 1) the illumination is supplied by a small incandescent lamp held in a metal cap A, in which is a small glass window, screwed to the end of the metal tube, B, which contains the telescope, C. At D is another small window, beneath which is the termination of the telescope, and an arrangement of prisms by which the image is projected to

cystoscope or catheterisation of the ureters (fig. 3). The instrument shown in the illustration is that of Max Nitze. A ureter-cystoscope bears upon its upper surface a covered slot or canal, in which fits a mandrel, terminating at the ocular end in a stopcock, while at the other extremity it protrudes through a small opening just behind the lens-window. A screw placed close to the eye-piece communicates to the end of the ureteral catheter a change in direction, illustrated in the diagram by the dotted lines. Through this mandrel is passed the elastic catheter when the instrument is in position in the bladder. When the ureteral catheter is *in situ* in the ureter, the instrument can be withdrawn leaving the catheter in place.

FIG. 2

the eye at C. The size of the instrument equals that of a No. 22 catheter (French gauge). The telescope magnifies the image several diameters, and the observer must consequently allow for this in his observations. The appearances, as in the laryngoscope, are reversed. The wires are connected at F to a rotatory plate, thus enabling complete rotation of the instrument, without the wires being carried with it. By this means one instrument only is necessary for a complete examination of the whole of the bladder, whereas formerly a cystoscope with a window on the under surface of the shaft was used for the base and trigonal area. The ocular rim should be made of ebonite, to avoid shocks should the eyebrows of the observer touch the instrument.

Cystoscopy in the female subject can be performed with the instruments already described. A shorter, wider cystoscope, however, can be employed, the visual field being thereby much enlarged. Howard Kelly, of Baltimore, uses plain metal tubes or vesical specula, through which light is thrown from a brow-mirror. This is practically an adaptation of the laryngoscope and otoscope to the examination of the bladder.

USE OF THE CYSTOSCOPE.—General anæsthesia in male subjects is desirable, but not essential. In the case of females local anæsthesia is sufficient. The patient should be placed on his back with the pelvis raised by means of a hard cushion. If general anæsthesia is declined or undesirable, the urethra and bladder can be rendered sufficiently anæsthetic

by cocaine (*see* ANÆSTHESIA, LOCAL). A drachm of a 2 per cent. solution of cocaine or of β -eucaine, if preferred, is injected into the urethra and retained there for five minutes. A soft rubber catheter is then passed and the bladder emptied. About two ounces of the cocaine-solution is injected into the empty bladder, and the catheter being slowly withdrawn, a drachm or two of the solution is left in the membranous-prostatic urethra. After five minutes' delay the solution is drawn off, and the bladder and urethra will be found in the majority of cases sufficiently anæsthetic for the examination to be pro-

to practise on a 'phantom-bladder.' By this means a certain amount of dexterity in the manipulation of the instrument is obtained.

In certain cases cystoscopy is not practicable. This is the case where the prostate is very much enlarged on its bladder-aspect. The window of the instrument in such a case may not pass from between the immensely enlarged lateral lobes. Hæmorrhage from an enlarged prostate disturbed by instrumentation is sometimes so great that no amount of washing will suffice to clear the medium and enable observations to be made. In other cases a large

FIG. 3

ceeded with. The bladder is filled with five or six ounces of a boric-acid solution, or warm boiled water, the cystoscope, which has been immersed in a weak carbolic-solution, is gently introduced, and the light turned on. The surgeon should first examine the neighbourhood of the ureteral openings and then the remainder of the bladder. The lamp must not be allowed to come in contact with the bladder-wall for any length of time, or scorching will result. If immersed in fluid but little heating occurs. The light should be turned off, however, for a few moments before the cystoscope is withdrawn. Experience is needed, as in the case of the ophthalmoscope and laryngoscope, to ensure the correct interpretation of the appearances observed. The writer has known an air-bubble mistaken for an ulcer, and a somewhat enlarged prostate for a malignant growth.

In the use of Kelly's tubes the patient is placed in the knee-elbow position, or the exaggerated lithotomy position. The urine is drawn off and the urethra dilated. A tube is passed and the obturator closing it removed. Air rushes in and balloons the bladder. The light is then thrown down the tube and the mucous membrane examined. With a finger in the vagina the posterior wall of the bladder can be pressed towards the end of the tube. Urethral catheters can be passed by the aid of this contrivance. As urine collects in the bladder it is removed by a long-necked sucker or exhaust-syringe. It will be seen that by this method the bladder is dilated with air instead of water, and that the bladder-walls are examined directly. In some cases the bladder is fixed by pelvic inflammation and air does not suffice to dilate it. To these cases the method is of course inapplicable.

It would be of little benefit to enumerate and describe the appearances seen with the cystoscope. These can only be learned satisfactorily by actual practice with the instrument. It is certainly of use

villous growth may wrap itself around the instrument and entirely obscure the view. In stricture of the urethra, it may be found impossible to introduce a cystoscope until full dilatation or internal urethrotomy enables the examination to be carried out.

F. SWINFORD EDWARDS.

BLASTOMYCETIC DERMATITIS.—*See* DERMATITIS.

BLEB.—A large vesicle or bulla, containing serous fluid, as in pemphigus, erysipelas, or burns and scalds. *See* BLISTER.

BLÉNORRHOËA, BLÉNORRHAGIA (βλέννα phlegm; and *ῥέω*, I flow βλέννα, phlegm; and *ῥήγνυμι*, I burst out).—These terms are most correctly used to express excessive flow of mucus from any mucous surface. By means of an affix, the locality or nature of the discharge is expressed e.g. *blenorrhoëa oculi, nasalis, urethralis*.

BLEPHARITIS (βλέφαρον, an eyelid).—Inflammation of the eyelids. *See* EYE AND ITS APPENDAGES, Diseases of.

BLEPHAROSPASM (βλέφαρον, an eyelid; and *σπᾶσμα*, a spasm).—Spasmodic movement or contraction of the eyelids. *See* EYE AND ITS APPENDAGES, Diseases of.

BLINDNESS.—Loss of sight. *See* AMAUROSIS and VISION, Disorders of.

BLISTER.—*SYNON.*: Bleb; Bulla; Fr. *Bulle* Ger. *Blase*.

DEFINITION.—A vesicle of the skin caused by the separation of the horny cuticle from the rete mucosum by the transudation of serous lymph beneath the former.

ÆTIOLOGY.—Blisters may occur in certain skin-affections such as pemphigus. They are also seen in the cutaneous manifestations of some of the acute infectious diseases, such as small-pox and chicken-pox. In addition they are met with under the influence of any cause which depresses the vitality of the integument, such as burns and scalds, or as an effect of powerful irritants, such as cantharides or the aniline-salts. Micro-organisms have been obtained from the contents of some vesicles, especially in certain forms of pemphigus.

DESCRIPTION.—A blister ranges in size from that of a pea to a turkey's egg. It is more or less convex according to the amount of exudation contained in it. It conforms in colour with that of its contents, being sometimes yellow or amber-coloured and transparent like serum, sometimes opalescent from the presence of pus, and sometimes red or purple from admixture with blood. The fluid of a blister is generally limpid and free, is sometimes held in the meshes of a delicate network resulting from the stretching of the cells lying between the rete mucosum and the horny epidermis. This is peculiarly the case in blisters developed under the influence of acute inflammation and especially in the dermatitis affecting workers in aniline. Blisters may be scattered over the body, or aggregated, or even single as in pemphigus.

TREATMENT.—Blisters are essentially asthenic in their nature and call for general tonic treatment. Locally they should be punctured so as to admit of the gradual escape of their contents and then dusted over with some antiseptic or absorbent powder such as oxide of zinc or boric acid.

ERASMUS WILSON.
E. F. TREVELYAN.

BLISTERING.—A therapeutic measure, which consists in the artificial production of blisters on the skin. See COUNTER-IRRITATION.

BLOOD, Transfusion of.—See TRANSFUSION OF BLOOD.

BLOOD, Abstraction of.—SYNON.: Bleeding; Blood-letting; Fr. *La Saignée*; Ger. *Der Aderlass*.

The withdrawal of blood from the body for therapeutic purposes may be effected (1) by the opening of a vein (venesection); (2) by leeches, and, more rarely (3), by scarification, and (4) by wet-cupping.

1. Venesection (see VENESECTION).—This procedure is employed in those cases in which extreme venous engorgement has produced so much dilatation of the right side of the heart that the cardiac muscle is unable to contract efficiently upon its contents and there is a danger of a cessation of its action during diastole. Such a condition may arise in valvular diseases of the heart, in acute and chronic diseases of the lungs, and in other conditions giving rise to the phenomena of asphyxia. In such cases the withdrawal of from four to eight ounces of blood may sufficiently relieve the intra-ventricular pressure on the right side of the heart, and enable it to contract more vigorously upon its contents. Venesection is not likely to be of much use if the walls of the heart are extensively degenerated; and it should always be avoided in the aged and the feeble. It is very rarely required in childhood. The cessation of the progressive improve-

ment in the character of the heart's impulse and of the radial pulse furnishes the best test of the moment when the flow of blood should be arrested.

Venesection is sometimes advocated in diabetic coma, uræmic convulsions, and other conditions believed to be due to poisons circulating in the blood. In these cases it is of doubtful service, and if employed should be supplemented by the infusion of normal saline solution.

2. Leeches.—From two to twelve leeches may be applied to any part of the skin, although care should be taken to avoid parts over which compression cannot easily be made should the subsequent bleeding be otherwise uncontrollable. The track of a superficial vein should also be avoided.

In applying a leech the skin should first be cleansed and the part wetted with a little boiled milk. A leech-glass facilitates the operation and ensures the application of the leech to the exact place selected. An average leech will at most abstract half an ounce of blood; as a rule the amount is distinctly less than this. If it is desired to continue the bleeding a fomentation may be applied after the leeches have fallen off; but should the bleeding continue too freely, dry aseptic dressings, styptics, or pressure may be applied.

Leeches are now principally employed for the relief of severe pain due to an acute local inflammation, and are thus used in iritis, pericarditis, appendicitis, and many other conditions.

3. Scarifying.—In this method a number of small parallel cuts, of a depth not exceeding an eighth of an inch, are made in the tissue from which it is desired to withdraw the blood. Scarifications are thus occasionally made in the cervix uteri and in the tongue, but the method is not so frequently resorted to as formerly.

4. Wet-cupping.—The method adopted in this almost obsolete procedure is at first the same as in dry-cupping (see CUPPING). The glasses are then removed, the raised portion of skin is scarified, the glass re-applied and finally removed when the desired amount of blood has escaped.

Wet-cupping is very rarely employed on the loins in nephritis, and on the chest when venesection or the application of leeches is impracticable.

JOHN HAROLD.

BLOOD, Clinical Examination of.—The systematic examination of the blood involves the estimation of (1) the number and condition of the red corpuscles including their hemoglobin-content; (2) the number of the white corpuscles and the relative proportion of the different kinds; (3) the number of blood-plates; (4) the rapidity of coagulation; (5) the specific gravity; (6) the alkalinity; (7) spectroscopic changes; (8) the serum-changes; and (9) the bacterial contamination.

Fortunately, the first two and the last two of these procedures generally give all the information required. In this article it is proposed to give only such a short and simplified account of them as will be found suitable to the requirements of the practitioner.

1. The obtaining of the blood.—The lobe of the ear is rubbed first with a wet and then with a dry towel; antiseptics are unnecessary. The ear is steadied and a moderately deep prick is sharply made with an ordinary three-sided surgical needle in the convex border of the lowest part of the lobe. The blood should flow freely and no pressure should

pipette is shaken, a drop deposited on the ruled disc of the counting chamber, and the cover-glass adjusted all exactly as before, but instead of counting the leucocytes in certain squares only, they are counted over the whole ruled space, i.e. 400 squares. The process is repeated with a second drop, and, if

vaseline or oil round the rim of the cover-glass, the leucocytes may be studied for a long time and a differential count be made even when the cells are still alive.

4. ESTIMATION OF THE HÆMOGLOBIN.—The total amount of hæmoglobin is diminished in all

anæmias, and its percentage is often lowered in proportion to the loss of red cells and often also independently thereof. Taking the percentage of hæmoglobin as the numerator, and the percentage of red cells as the denominator, we get a fraction $\frac{\text{Hb. percentage}}{\text{R.C. percentage}}$ which represents the relative richness of the individual corpuscles, and is conveniently spoken of as their colour-index. It is = 1 when normal. It is lowest in chlorosis, where the loss in corpuscles is often comparatively slight, and highest in pernicious anæmia, where alone of all anæmias the hæmoglobin is usually relatively increased, although the diminution in red cells is so great. In such cases the colour-index often exceeds 1.

The percentage of hæmoglobin is estimated by means of a hæmoglobinometer. Oliver's (fig. 2) is preferable to that of Gowers or of von Fleischl. It consists of 12 tinted glass discs arranged in two rows and corresponding to definite percentages of hæmoglobin, ranging from 10 to 120 (a). The intervening percentages are ascertained by the help of small squares of tinted glass known as 'riders,' and having values of 5 per cent., 2·5 &c., which being placed upon any of the primary discs deepen its tint. The blood is collected in a short pipette (c) which is first cleaned out and dried by passing through it a needle threaded with darning cotton. The blood should fill the pipette in an unbroken column. The rubber nozzle of the mixing pipette (d) previously charged with water is fitted over its blunt end, and the blood is gently washed out with the

first few drops of water into the mixing chamber (e). The water is gently added drop by drop until the chamber is full to the brim, the handle of the pipette (c) being used as a stirrer. An oblong piece of colourless glass is provided, and this is now adjusted as a cover-glass, and the small air-bubble which forms beneath it shows that the cell has been properly filled. The blood-chamber is now brought close to the tinted discs for comparison. The reading is done by candle-light (small Christmas candles are best) placed about four inches away,

FIG. 2

necessary, with a third, an average being taken as before. In this case,

$$\frac{\text{No. of leucocytes in 400 squares} \times 10 \text{ (the dilution)} \times 4,000}{400}$$

= the no. of leucocytes in 1 c.mm. of blood. 7,000 to 8,000 may be taken as the average in health. By using Toisson's diluting fluid, or Sherrington's, viz. Ehrlich's methylene blue, 0·1 grm.; sodium chloride, 1·2 grm.; neutral potassium oxalate, 1·2 grm.; distilled water, 300 c.c.; and painting

and the same above the level of the discs and blood-chamber, and placed so that the light falls upon and is reflected from both equally. In daylight this must be done in a dark place. A set of discs can be procured for use by daylight, but they are less accurate. All side-light is excluded by using the flexible camera-tube. Short observations of about ten seconds each should be made, as the eye is thereby rested and can better appreciate delicate differences. If the colour of the blood-chamber exactly corresponds to any one of the standard series, the percentage of hæmoglobin can at once be given, but if it lies intermediate between any two, it is placed opposite the lower, upon which riders are placed until this approaches the tint of the blood-chamber.

5. The specific gravity of the blood gives us the same information as the hæmoglobin-value, and the method of ascertaining it need not be described.

6. THE EXAMINATION OF THE SERUM.—The serum-diagnosis of typhoid fever, cholera, plague, and other diseases will be found referred to in the articles on those diseases, in which the utility of the method has been established.

7. THE DETECTION OF BACTERIA IN THE BLOOD.—Bacteria are rarely present in such numbers as to be capable of detection in films, and usually can only be obtained by cultures: the *Bacillus anthracis* and the *Spirillum* of Relapsing fever are, however, notable exceptions to this rule. The skin over the flexor aspect of the elbow is sterilised and then washed with boiled water to remove all traces of the sterilising solutions. Pressure is exerted on the arm above the elbow to bring out the veins. The needle of a hypodermic syringe (previously sterilised by boiling) is inserted into the most prominent one, and about 2 c.c. of blood are drawn into the syringe by gently raising the piston. The needle is then withdrawn and the blood at once expelled into a sloped agar or blood-serum tube so that it runs over the surface of the medium and collects a little at the bottom. The tubes are incubated, and any culture obtained is examined in the usual ways. A pad of sterilised gauze is placed over the puncture. The discovery, in this way, of pneumococci, staphylococci, gonococci, or other bacteria, not only assists in the diagnosis, but warrants a grave prognosis.

III. The Examination of Fixed Blood.—This is the most generally useful and valuable of all the methods, and should be practised in all cases whether any other method is used or not. It enables us after some practice not only to estimate roughly the number and condition of the red cells, their hæmoglobin-content, and the number of the white cells; but it also brings out the finer morphological structures of the latter and tells us the relative numbers of the different varieties. It is carried out as follows:

I. THE PREPARATION OF THE FILMS.—A small drop of blood is received upon the centre of one clean cover-glass (*v. supra*), which is then gently dropped, blood downwards, upon another, when the blood will spread itself out in an even layer between the two. A corner of each is now grasped in a pair of forceps and they are gently slid apart and allowed to dry, face upwards, in the air, care being taken that they are never pressed together either before or during separation, and that they are afterwards protected from dust. Beginners almost always take too large a drop, and hence they

may use the ungummed edge of a cigarette-paper or bit of gutta-percha tissue, which is moistened in the drop of blood and then rapidly drawn along the surface of a slide; or they may transfer a correct drop to the cover-glass by a measured platinum loop. Whichever plan is adopted, the procedure must be quickly carried through.

2. THE FIXATION OF THE FILMS.—(a) *By formalin-vapour*.—The films are exposed to the vapour of 40 per cent. formalin for five minutes. The formalin may be put in any convenient dish, e.g. the half of a Petri capsule, a watch-glass, or even a wine-glass. In any case, the top of the dish or glass is closed by a cover (e.g. of cardboard), with a central aperture large enough to enable the cover-glass to be placed film downwards and exposed to the vapour of the formalin. The films are next exposed to the air but protected from dust for some time, as any traces of formalin in them interfere with staining. (b) *By heat*.—This may be applied in various ways, e.g. by passing the cover-glass, film upwards, about twenty times through the flame of a Bunsen lamp, but is best done by placing the films in a dry steriliser, or some simple substitute, and gradually raising the temperature to 120° C., which is kept up for ten minutes to two hours before removing the films. Even better results may be obtained by gradually raising the temperature to 150° C., allowing to cool, and then removing the films. This takes generally about ten minutes. Insufficient heating is a commoner error than overheating. (c) *By absolute alcohol and other (equal parts)*.—The films are simply placed therein for at least half an hour. They are then taken out and dried in the air. This method is most successful with the red cells, but also gives good results with the white.

3. THE STAINING OF THE FILMS.—For good results, Gruber's stains, which are now readily obtainable, should be used. A combination of a basic and acid aniline stain, such as methylene blue and eosin, or Ehrlich's triacid stain must be used. Both give beautiful and reliable results. The first is applied as follows: (1) Place the film in a two per cent. watery solution of eosin for two to four minutes, (2) wash and dry, (3) dip in water, (4) place in saturated watery solution of methylene blue for half to two or three minutes according to result observed (test by placing under microscope at intervals), and (5) wash in water, dry, and mount in Canada balsam. The red cells are stained pink, the nuclei of the white cells are coloured blue, and their coarse granules deep pink. These are therefore called *eosinophile*; while the fine granules, staining pale pink or remaining colourless, are called *neutrophile*. Ehrlich's triacid stain is a mixture of orange G., acid fuchsin, and methyl green combined in varying proportions by different workers. The stain is applied for several minutes, and the film is then washed in water, dried and mounted. The red cells are stained orange, the nuclei of the white various shades of blue, the eosinophile granules copper-colour, and the neutrophile granules a violet or pink tint.

R. F. C. LEITH.

BLOOD, Morbid Conditions of.—In considering this subject the following arrangement will be adopted.

A. CHANGES IN THE CORPUSCULAR ELEMENTS.—I. The red corpuscles. II. The leucocytes. III. The blood-plates.

B. CHANGES IN THE FLUID PART OF THE BLOOD.—I. Those affecting the blood as a whole, e.g. alterations in volume, specific gravity, and chemical reaction. II. Those due to variations in normal chemical constituents or to the presence of abnormal substances.

A. CHANGES IN THE CORPUSCULAR ELEMENTS.

1. **The Red Corpuscles.**—Variations in the red corpuscles are of common occurrence in disease, and these may be considered under the following heads: (a) Number per c.mm.; (b) Size and shape; (c) Richness in hæmoglobin; (d) Staining-reaction and other physical characters; (e) The appearance of abnormal elements in the blood, especially nucleated red blood-corpuscles.

(a) *Variation in number.* Although the total number cannot be readily ascertained, much is known regarding the variations in a given quantity of blood, 1 c.mm. being usually taken as the unit. *Polycythæmia*, or an increase above the normal number of 5,000,000 per c.mm., is met with in a few conditions. 1. What may be called a physiological increase takes place when the person ascends to higher altitudes, an increase of about 2,000,000 being observed at a height of 6000 feet. This increase begins within a few hours, and is said to be due to an increased number of small red blood-corpuscles and poikilocytes, which are probably formed by splitting or budding of the original corpuscles; there is no increase of the hæmoglobin. Some days afterwards there is an increased number of red blood-corpuscles of normal appearance, and the percentage of hæmoglobin also rises. These changes are supposed by some observers to indicate an increased formation of red corpuscles—a compensatory change brought about by the diminished supply of oxygen. Others, however, maintain that concentration of the blood by loss of water is sufficient to account for the phenomenon. On return to a lower level, the number of red corpuscles shows a comparatively rapid fall. 2. In general chronic venous congestion, e.g. in mitral and congenital heart-disease, there is often an increase in the red blood-corpuscles, and sometimes this is very marked, a count of 7,000,000 per c.mm. being by no means exceptional. This is probably brought about by altered conditions of the circulation, and is hardly to be regarded as of compensatory nature. 3. In poisoning with phosphorus and with carbonic oxide there is usually polycythæmia. 4. In conditions in which there is a large withdrawal of fluid from the blood, e.g. in cholera, a varying degree of polycythæmia results.

Oligocythæmia, or a diminished number of blood-corpuscles, is of common occurrence. When a single large hæmorrhage occurs, usually about a day elapses before the number of red blood-corpuscles per c.mm. reaches its lowest level. This of course corresponds with the period when the restoration of the fluid has been completed by absorption, partly from the tissues, partly from the alimentary canal. Then follows the period of regeneration, in which the number of red blood-corpuscles rises—slowly at first, more rapidly later—until the normal number is regained. The percentage of hæmoglobin is, however, not restored until some time later, the corpuscles in the meantime showing a deficiency in hæmoglobin. In healthy animals more than a million corpuscles per c.mm. may be restored in the course of a week, and sometimes the process is

equally rapid in the healthy human subject. More frequently, however, the restoration is much more gradual. After a single large hæmorrhage there may be practically no alteration in the appearance of the red blood-corpuscles with the exception that some may show the polychromatophile reaction (*vide infra*). If, however, hæmorrhages are repeated, and a chronic oligocythæmia is produced, variations in the size and shape of the corpuscles appear, many corpuscles being under-sized and containing a relatively smaller amount of hæmoglobin. Nucleated red blood-corpuscles of normoblastic type may be present in the general circulation. Leucocytosis and increase of the blood-plates usually accompany these changes. When such a condition has been established, restoration occurs much more slowly than in the case of a single large hæmorrhage. The source of red blood-corpuscles in the adult is from the nucleated red blood-corpuscles in the bone-marrow, and after hæmorrhages the number and proliferation of the latter are much increased.

Of the various diseases attended with oligocythæmia pernicious anæmia is that in which the most extreme degree is met with. The number frequently falls below a million (*see ANÆMIA, PERNICIOUS*). In chlorosis the number is in many cases only slightly reduced (*see CHLOROSIS*). Oligocythæmia is common in many chronic diseases associated with a greater or less degree of cachexia, e.g. malignant disease, phthisis, prolonged suppurations, lead-poisoning, chronic gastric catarrh, &c. Such cases of oligocythæmia are included under the term 'secondary anæmia.' The greatest fall is probably met with in cancer of the alimentary canal, the number sometimes falling to 1,000,000 per c.mm. In chronic malaria the anæmia resulting from the direct destruction of red corpuscles may be very extreme, and may in fact reach a similar or even lower level. In the production of oligocythæmia in these various diseases, excessive or abnormal destruction and deficient formation of red corpuscles are variously concerned (*see ANÆMIA, PERNICIOUS; CHLOROSIS*). After acute infective fevers and various toxic conditions, a distinct fall in the number of corpuscles may be observed. This is in chief part due to destruction of the red corpuscles, distinct evidence of which may be found in the spleen; the presence of pathological urobilin in the urine is usually regarded as another indication of the same process.

(b) *Variations in size and shape* are often associated. Corpuscles larger than normal are usually called *megalocytes*; those smaller than normal, *microcytes*. Megalocytes are common in pernicious anæmia, the round corpuscles reaching 10 or 12 μ in diameter, the oval corpuscles 14 μ or even more in their long axis. In fact, although microcytes are also common, the average size of corpuscles in this disease is usually above the normal, and there is an increase in the amount of hæmoglobin per corpuscle. In other anæmias, variations in size also occur, but megalocytes are relatively few in number, microcytes being much more numerous; as a result the average size of corpuscles is diminished. Microcytes may be 4 μ in diameter, or even less. Abnormally shaped corpuscles or *poikilocytes* (*see fig. 5*) may be met with in practically any variety of oligocythæmia when it is severe. Their presence in itself has therefore no diagnostic significance. Poikilocytosis, however, is most striking in cases of pernicious anæmia, where the presence of a great variety of forms is a striking feature. In chlorosis

it is by no means uncommon, and in severe post-hæmorrhagic and in cachectic anæmia the presence of numerous small poikilocytes is often noteworthy. The significance of such changes in shape is doubtful. According to Ehrlich's view it is to be regarded as a salutary process in which splitting or budding of the corpuscles takes place in order to provide an increased respiratory surface; hence he called these irregular forms *schistocytes*. According to another view the condition is simply to be interpreted as the effect of impoverished nutrition on the stroma of the red blood-corpuscles. Poikilocytes can be produced artificially by carefully heating the blood outside the body. The smaller microcytes are probably formed by the same agencies as the poikilocytes, there being no evidence that they represent younger corpuscles which afterwards undergo enlargement.

(c) *Variations in hæmoglobin*.—The amount of hæmoglobin in a given volume of blood (see BLOOD, Examination of) is expressed as a percentage of the normal. The amount of hæmoglobin per corpuscle, or 'colour-index,' is obtained by dividing the percentage of hæmoglobin by the percentage of corpuscles, taking the normal as $\frac{100}{100} = 1$. In the various anæmias the percentage of hæmoglobin is diminished, but to a different extent. In chlorosis we find a much greater diminution of the hæmoglobin than of the number of red corpuscles (see CHLOROSIS). In pernicious anæmia, on the other hand, the hæmoglobin is less diminished than the number of red blood-corpuscles, and the colour-index is raised, the average being 1.05 to 1.1. In the secondary anæmias and in the so-called simple anæmias the colour-index is slightly less than normal, though not so low as in chlorosis; in leucocythæmia also it is generally a little under the normal. As already stated, the colour-index is also lowered after hæmorrhages, and the normal condition is not regained until some time after the number of red corpuscles has reached the normal level.

(d) *Alteration in staining-reaction, &c.*—Of these the most important is what is known as 'polychromatosis,' 'polychromatophile regeneration,' or 'anæmic degeneration,' a condition in which the normal staining-reaction of hæmoglobin is diminished or lost. Thus in staining with Ehrlich's eosin and hæmatoxylin, the affected corpuscles are coloured violet or dull blue instead of a pure pink colour (fig. 5A). At the same time they have diminished consistence, their form being less easily preserved than that of the normal corpuscles; thus in film-preparations they often show an irregular margin. According to one view this is a degenerative change due to impaired nutrition. Another view is that these corpuscles are young forms somewhat labile and deficient in hæmoglobin, and in support of this view it has been pointed out that various nucleated red blood-corpuscles show in their protoplasm the same staining-reaction and other alterations. The matter cannot be definitely settled, but it is probable that some of the corpuscles showing the change mentioned are really in a degenerated state. The conditions in which this change is met with are chiefly the various anæmias and cachectic conditions.

A diminished consistence with increased adhesiveness, whereby the corpuscles tend to clump into irregular masses, may be observed in some severe toxic conditions, malignant jaundice, typhus fever, &c. It may be added that absence of rouleaux-

formation when the blood is shed is common where there is marked oligocythæmia.

One other subject may be referred to here, viz. alterations in the resistance of the red corpuscles to various physical and chemical agencies, e.g. heat, electricity, dilution of the plasma. In the case of the last-mentioned, which has been most studied, the greatest dilution which may be made without producing diffusion of the hæmoglobin is obtained, this being called the 'isotonic point,' or 'isotonic concentration.' The isotonic point, which in the case of normal blood is about .45 per cent. as regards sodium chloride, will be of course higher when the resistance of the corpuscles is diminished. This has been found to be the case in various toxic and infective conditions, in anæmia, &c. Accordingly these results obtained are not of much diagnostic value. In jaundice on the other hand the isotonic point is lowered.

(e) *Presence of nucleated red corpuscles, &c.*—These cells, which are present only in the bone-marrow in the normal state, appear in the circulating blood in a number of conditions of disease. In the medullary form of leucocythæmia they are practically always present and are met with in greater number than in any other disease. In some cases three or four may be found in every microscopic field. In lymphatic leucocythæmia, on the other hand, they are very scanty, and in fact often entirely absent till a late period of the disease. In pernicious anæmia the presence of nucleated red blood-corpuscles is of almost invariable occurrence, though they may be few in number and difficult to detect. In severe post-hæmorrhagic anæmia, they may be fairly numerous, and in cachectic anæmia they may appear in the blood, though usually in very small numbers. They may also be present in severe malarial anæmia. In chlorosis, on the other hand, their presence is exceptional. Lastly, in severe toxic and infective conditions, nucleated red blood-corpuscles may occasionally be detected, usually in association with myelocytes; the presence of these two classes of cells indicates a grave condition.

Nucleated red blood-corpuscles are usually divided into two main classes, *normoblasts* and *megaloblasts* (fig. 6). Two other varieties, *microblasts* and *poikiloblasts*, are also distinguished. A normoblast measures as a rule 8–9 μ in diameter, and usually contains a single spherical nucleus, about 3–5 μ in diameter, often more or less eccentric in position. The larger nuclei show a coarse reticulum of chromatin; those of smaller size appear more or less homogeneous. Occasionally there are two or even more nuclei of small size. In all cases the nuclei stain very deeply with nuclear stains. The megaloblast is of large size, sometimes reaching 12 μ or even more in diameter. Its nucleus is fairly large and stains faintly, sometimes being diffusely stained, sometimes showing a fine reticular or granular appearance. It must be noted, however, that some megaloblasts have a fragmented nucleus, with deeply staining chromatin. The protoplasm of the megaloblasts in film-preparations often shows an irregular margin and gives the polychromatophile reaction. Of the various conditions noted, pernicious anæmia is the only disease in which megaloblasts are met with as a rule. This circumstance agrees with the fact that the average size of red corpuscles in this disease is raised. Ehrlich believes that in pernicious anæmia the formation of red blood-corpuscles is of a different type (viz. the megaloblastic

type) from that in other diseases. Cases of this disease vary very much as regards the number of megaloblasts present. In some instances they are comparatively numerous, in others it may be extremely difficult to find any. The prognosis is considered by some observers to be more serious in the former condition. It may also be mentioned that in the anæmia produced by the *Bothriocephalus latus* megaloblasts may be present in the blood, the various changes closely resembling those in pernicious anæmia. Here, however, the prognosis is much less grave, as cure often results on the removal of the parasite. In the other diseases mentioned the nucleated red blood-corpuscles are of the normoblastic type. They are usually comparatively scanty, but in certain states, believed to be associated with increased regeneration and called 'blood-crises,' a large number of nucleated red blood-corpuscles may appear in the circulation. As a general rule the presence or absence of normoblasts in the conditions specified cannot be said to have much prognostic significance.

Microblasts are small nucleated red blood-corpuscles 5-6 μ in diameter. They are sometimes found along with megaloblasts in pernicious anæmia. A *poikiloblast* is merely a nucleated red blood-corpuscle of irregular form and may be of the normoblastic or megaloblastic type. It may further be noticed that the appearance of nucleated red blood-corpuscles in the circulation occurs more readily in earlier years than in adult life.

As other abnormal structures we may mention irregular fragments of red corpuscles, which have been observed in the blood after severe burns and after certain poisonings, e.g. with pyrogallol acid. In hæmoglobinæmia (*vide infra*) decolourised red corpuscles may sometimes be detected, their stroma presenting a pale shadow-like appearance (*shadow-corpuscles*).

II. The Leucocytes.—In connection with changes in the leucocytes in disease, we have to consider (1) variations in the total number; (2) variations in the relative proportions of the different varieties; and (3) the presence of abnormal forms. The measurements that will be given are those obtained from the fresh blood; in a dried film the leucocytes may appear larger, owing to flattening.

In normal conditions the number per c.mm. may be said to be 6,000 to 10,000, though it may sometimes pass beyond these limits. The chief varieties (*see fig. 1*) are:—(a) Lymphocytes, about 7-8 μ in diameter, with spherical and deeply staining nucleus and scanty protoplasm; non-amœboid and non-phagocytic; numbering about 20-22 per cent.; (b) Large mononuclear or hyaline leucocytes, 9-12 μ in diameter, with spherical, oval, or slightly indented nucleus; in some the nucleus is more lobulated, the so-called 'transitional forms.' The protoplasm is more abundant and the nucleus stains less deeply than in the case of the lymphocytes. They are more or less amœboid and phagocytic, numbering 4-5 per cent. (c) Finely granular neutrophile or polymorphonuclear leucocytes, 9-10 μ in diameter. The nucleus is single, but much lobulated so as to present a great variety of forms; hence these leucocytes are often spoken of as 'multinucleated.' The nucleus is rich in chromatin and stains deeply. The protoplasm contains granules which give a 'neutrophile' reaction, though they can also be stained with acid dyes, that is, are feebly 'oxyphile.' These leucocytes are actively amœboid and phago-

cytic; they number about 70 per cent. (d) Coarsely granular or eosinophile leucocytes. The nucleus is polymorphous and the granules large, with strong affinity for acid dyes. They are actively amœboid, but not as a rule phagocytic. They number 3-5 per cent. (e) Leucocytes with mast-cell granules. These are coarse granules which stain deeply with basic dyes and give a metachromatic reaction, staining, for example, a violet tint with methylene blue. They are rarely present in normal blood.

LEUCOCYTOSIS.—Under normal conditions slight increase in the number of leucocytes occurs in physiological states, e.g. after a meal, especially when rich in proteids, during pregnancy, and after parturition. Such increase—physiological leucocytosis—rarely reaches more than 25 per cent. of the normal. In numerous pathological conditions the number undergoes marked variations. When it rises above normal the term *leucocytosis* is applied (leucocythæmia, which will be described separately, being excepted); the converse condition, a degree below the normal, is called *leucopenia* or *leucocytopenia*. As a distinct leucocytosis is nearly always due to an increase of the neutrophile leucocytes, the term 'leucocytosis' or 'ordinary leucocytosis' is employed as equivalent to a neutrophile leucocytosis. Lymphocytosis signifies an actual increase of the lymphocytes, though it is often employed when there is a percentage increase of these cells. According to the latter significance it will be present when there is a marked fall in the number of neutrophile leucocytes. Eosinophile leucocytosis or eosinophilia signifies an increase of the eosinophiles; this is in most cases approximately indicated by the percentage of these cells. We shall now consider the conditions in which these variations occur.

1. Ordinary or neutrophile Leucocytosis.—As already stated, the essential factor is the increase of the neutrophile leucocytes (*fig. 2*). The degree varies in different cases. 15,000 and upwards per c.mm. may be considered a well-marked leucocytosis, 30,000 and upwards an extreme leucocytosis, though 50,000 or even more may sometimes be reached. The proportion of neutrophiles may rise as high as 90 per cent. or even higher. The conditions of occurrence, which are both numerous and various, may be considered under the following heads:—(a) *Inflammatory and infective leucocytosis*. Here may be included a large number of bacterial infections, and also some of the specific fevers in which the virus has not been discovered. Leucocytosis is usually well marked in pneumonia, erysipelas, diphtheria, scarlet fever, plague, small-pox in the suppurative stage, in many acute inflammatory conditions, especially when suppuration is present, e.g. in pyæmia, peritonitis, arthritis, &c., and also in many spreading gangrenous conditions. The degree varies in different cases of the same disease and shows irregular fluctuations during its course. In contrast to the neutrophiles in these conditions the eosinophiles are diminished in number or may be absent; in pneumonia, for example, it is often impossible to find any of these cells in the ordinary course of the disease. On the subsidence of the disease the leucocytosis disappears: when defervescence occurs by crisis the fall is rapid, when by lysis it occurs more slowly. The evacuation of a large quantity of pus is usually accompanied by a rapid fall. A fall in the number of leucocytes without improve-

film-preparations stained with eosin and methylene blue. Figs. 1—4 $\times 500$. Figs. 5 and 6 $\times 750$.

ment of the general condition has however quite a different significance, and it may be stated that absence of leucocytosis or disappearance of the leucocytosis without general improvement is an unfavourable sign in the conditions mentioned. This fact is of prognostic value in pneumonia, diphtheria, and in some cases of septicæmia. Towards the end of the leucocytosis, the hyaline leucocytes may show increase; and after its subsidence the eosinophile leucocytes reappear in the blood, and their percentage may even rise above normal. (b) Under the heading *toxic leucocytosis* may be included a number of conditions in which there is no evidence of infection, e.g. malignant jaundice, lead-poisoning, chronic Bright's disease. Here the leucocytosis has the same characters, but is usually less marked than in the previous group. (c) *Post-hæmorrhagic leucocytosis*. After a large hæmorrhage leucocytosis is usually well marked within three or four hours, that is, during the period when the fluid part of the blood is being restored. If the hæmorrhage is not repeated, the leucocytosis diminishes, and may be absent during the time of blood-regeneration. When marked anæmia with cachexia results from repeated hæmorrhages, there is usually a well-marked leucocytosis of chronic nature. (d) *Cachectic leucocytosis*. This is probably an instance of chronic toxic leucocytosis. It is well seen in the cachectic stage of malignant disease.

2. *Eosinophile leucocytosis or eosinophilia*.—The diseases in which this condition is present form quite a distinct class from those in which ordinary leucocytosis occurs. The following are the most important of them: (a) In certain acute and chronic diseases of the skin, pemphigus, psoriasis, urticaria, &c. It is also of interest to note that eosinophiles are also numerous in the local tissue lesions in these diseases. (b) In *asthma*, more especially during the paroxysms, the proportion of eosinophiles may reach 10–20 per cent.; eosinophiles are also abundant in the bronchial secretion. (c) In infections with *parasitic worms*, especially round worms, e.g. *Trichina spiralis*, *Ankylostoma*, and others, the number of eosinophiles may run as high as 50 per cent. of the total leucocytes. (d) In some cases of *malignant growths in the bone-marrow*. The most important condition under which the proportion of eosinophiles is less than normal is an acute neutrophile leucocytosis, when, as already mentioned, they may practically disappear from the circulating blood.

3. *Lymphocytosis*.—An actual increase of the lymphocytes (apart from lymphocythæmia) is comparatively rare. It has been found in certain malignant growths in the lymphoid tissues, in some cases of chronic gastric and intestinal catarrh; and it is sometimes present in whooping cough. As a rule it occurs more readily in children than in adults. A relative lymphocytosis will be present in those conditions in which the number of neutrophile leucocytes falls, as will be explained below.

4. *Increase of hyaline leucocytes*.—These cells have been less completely studied as regards their variations than the other classes. An increase is, however, common towards the end of an ordinary leucocytosis, e.g. in acute pneumonia about the time of the crisis. Their number is often increased in malarial fever, especially when of some duration, and an increase has also been noted in cases of gout.

LEUCOPENIA.—(a) In a certain number of *acute infective conditions*, the proportion of leucocytes remains constant or is diminished. Leucocytosis is usually absent in typhoid fever, in measles, in acute tuberculosis without cavity-formation, and in most cases of influenza. In typhoid fever there is usually marked leucopenia, especially during the late stages, when a number of 3,000 is not uncommon. Again, in various affections, where leucocytosis is the rule, leucopenia may supervene, the condition then becoming one of great gravity, e.g. in pneumonia and septicæmia. Conversely, in the diseases just mentioned, leucocytosis may appear if some suppurative or inflammatory conditions become superadded as a complication. (b) *Leucopenia occurs in a number of chronic diseases*. In pernicious anæmia, in chlorosis, in purpura, in hæmophilia, and in some cases of splenic anæmia, the number is almost invariably below the normal. In pernicious anæmia, for example, the number is often about 1,000 per c.mm., though some cases run their course with a considerably higher number. Here again the diminution is chiefly on the part of the neutrophile leucocytes, although in extreme cases all varieties may be affected. The condition of the leucocytes in these anæmic conditions presents a contrast to that in the secondary anæmias, where leucocytosis is the rule.

PRESENCE OF ABNORMAL ELEMENTS. (a) *Myelocytes*.—These are large cells measuring up to 15μ in diameter, and normally present only in the bone-marrow. They have a large oval, or slightly indented, nucleus, which stains comparatively faintly. The protoplasm contains fine granules, giving a neutrophile reaction, like those in the finely granular leucocytes. As will be shown below, they occur in large numbers in the medullary forms of leucocythæmia. Small numbers may, however, appear in the blood in certain other diseases. They have been observed, for example, in pernicious anæmia and in some cases of secondary anæmia due to malignant disease, and they also appear towards the termination of severe infective conditions, usually when the number of leucocytes is small. In the last group of diseases their appearance has on the whole a grave significance. Very often a few nucleated red blood-corpuscles can be detected along with them.

(b) *Cells with mast-cell granules*.—Although these have been noticed in normal blood, their presence must be considered as exceptional. In leucocythæmia these cells may be numerous, and a considerable proportion may be present in certain wasting diseases.

Significance and nature of leucocytic variations.—Only the most important facts can be enumerated. The non-granular and granular cells are affected by different conditions and must be considered as physiologically distinct. The granular cells multiply by mitotic division only in the bone-marrow, the non-granular cells in the lymphoid tissue throughout the body. The granular cells (neutrophile and eosinophile) are guided in their variations by chemotaxis, the two classes being differently affected by different substances, i.e. the neutrophiles are attracted by substances which may have no effect on the eosinophiles, and *vice versa*. The local migration into the tissue is brought about by chemiotactic substances, and when such substances are absorbed in large quantities into the blood, they exert a corresponding action on the

increased, but when there have been many hæmorrhages, with marked anæmia as a result, coagulation occurs more slowly than normal. In scurvy and many purpuric conditions, the coagulation-time is lengthened, though the amount of fibrin is usually increased (Hayem). In hæmophilia coagulation is considerably delayed, the clot is imperfectly formed, and fibrin is said to be decreased, though on the last point more definite information is desirable. In urticaria and in many other conditions with serous exudation, coagulation takes place more slowly than normal (Wright).

(b) *Presence of free hæmoglobin, &c.*—The term hæmoglobinæmia is applied when there is free hæmoglobin in the plasma. Its presence may be shown by centrifugalising the blood or by allowing it to stand and obtaining the serum in the usual way, the serum being of course tinted. This condition reaches its highest degree in paroxysmal hæmoglobinuria, the free hæmoglobin being rapidly excreted by the kidneys. Hæmoglobin has also been found free in the serum in a number of severe infective or toxic conditions, e.g. icterus gravis, malignant scarlet fever, typhus fever, snake-poisoning. This may be looked upon as an example, in more severe form, of the tendency which the hæmoglobin has to diffuse out of the red blood-corpuscles after death in many infective diseases. In poisoning with a number of substances, not only is the hæmoglobin set free in the circulation, but is also converted into methæmoglobin, the condition being called *methæmoglobinæmia*. As examples of such poisons may be mentioned chlorate of potassium, many nitrites (nitro-benzol, nitrite of amyl), pyrogallol acid, ferrocyanides, &c. In such conditions fragments of red blood-corpuscles or their decolourised stroma may also sometimes be detected microscopically in the blood. In poisoning by carbonic oxide the blood has a light red colour owing to the combination of this gas with the hæmoglobin. In sulphonal-poisoning, hæmatoporphyrin is present in the urine and has also been detected in the blood in some cases. See SPECTROSCOPE IN MEDICINE.

(c) *Increase of Urea &c.*—In fevers and other conditions in which there is an increased production of urea and other nitrogenous extractives, no marked increase of these substances occurs in the blood owing to their rapid excretion. Such increase may however be met with in Bright's disease, especially in the catarrhal form with marked albuminuria and deficiency of urine, and to a still greater degree when there is uræmia. In health the amount of urea in the blood is about '015 per cent., while in uræmia it may rise to more than twenty times this proportion. Urea in itself is relatively non-toxic, but the fact just stated is of importance as indicating the probable retention in the blood of some other toxic substance. Other nitrogenous extractives are increased along with the urea, both in the blood and in the dropsical exudations, but it has so far been found impossible to reproduce the characteristic symptoms of uræmia by the injection of any of these substances. The hypothesis that uræmia is due to the presence of ammonium carbonate in the blood has not been substantiated by direct observations. In puerperal eclampsia, it may be mentioned, there has been found to be only a slight increase of urea. See URÆMIA.

Uric acid (urates) in the blood.—In normal conditions the amount of uric acid (in combination) is so

small that it cannot be detected by chemical means. In gout there is relatively a considerable quantity; Garrod found '00175–'0025, per cent., and though estimations by improved methods have given rather lower figures, the general result has been confirmed. The presence of uric acid can usually be demonstrated by the 'thread-method' (see GOUT). The presence of uric acid is, however, not peculiar to gout, as it has been observed in other diseases, e.g. in cases of severe anæmia, in pneumonia, in cardiac disease with dyspnoea, and in nephritis. In leucocythæmia it has been found by some observers, while others have obtained negative results; the presence of hypoxanthin and other members of the xanthin series in the blood, and increase of uric acid in the urine, are, however, well-established facts, and usually ascribed to the increased disintegration of nuclein contained in the leucocytes. In the other conditions mentioned, diminished oxidation and interference with excretion may also be variously concerned in the presence of uric acid in the blood.

(a) *Increase of Fat—Liphæmia.*—The amount of fat in normal conditions becomes more abundant after meals; it is also increased in a variety of diseased conditions. In diabetes it was found many years ago that on post-mortem examination in some cases the fat was so abundant that it formed a distinct milky scum on the surface, and the name 'liphæmia' was applied to the condition. Later observations have shown that in a certain proportion of cases of this disease liphæmia can be detected during life, though often in very slight degree; in some cases of diabetic coma it has been found well marked. Its presence can be shown by filling a fine glass tube with blood and examining microscopically the superficial layer after the blood has been allowed to stand for some time. An oil-immersion lens should be used, as the droplets are sometimes very minute. It can also be demonstrated by staining film-preparations with osmic acid. The exact circumstances determining the presence of liphæmia and regulating its degree in diabetes are unknown. Liphæmia has also been found to occur in cases of obesity, phthisis, alcoholism, some fevers, e.g. typhus, and in conditions of dyspnoea. Fatty acids, in combination as salts, have also been demonstrated in the blood in various fevers, in some cases of diabetes, in leucocythæmia, and in acute yellow atrophy of the liver, their presence being supposed to be due to defective oxidation. Fat may also enter the blood in comparatively large droplets in fractures of bones and give rise to capillary embolism. See EMBOLISM.

(e) *Increase of Sugar—Melithæmia.*—In normal conditions the amount of dextrose in the blood is about '015–'05 per cent., showing variations according to the food &c. In diabetes the amount is greatly increased, rising in severe cases to '5 per cent. Along with this the specific gravity of the serum is high (unless there is marked cachexia), and the alkalinity tends to be diminished, being markedly so in the condition of diabetic coma, owing to the formation of diacetic, oxybutyric, and other fatty acids. The view that acetone plays an important part in the stage of coma is now generally discarded. In some cases there is a marked increase of fat (*vide supra*). In poisoning with chloroform, morphine, curare, nitrites, carbonic oxide, &c. the amount of sugar in the blood is distinctly increased. On the

other hand, in 'phloridzin' diabetes, though a large quantity of sugar is excreted by the kidneys, the amount in the blood does not exceed the normal. The percentage of sugar has been found to be raised in some cases of cancer, sometimes to three times the normal, and to be diminished in nephritis (Freund and Trinkler).

(f) *Cholamia*.—This condition may be said to result from the absorption of constituents of the bile by means of the lymphatics, and is manifested by the presence of jaundice. Formerly a 'hæmatogenous' form of jaundice was believed to occur in certain diseases, but it now appears that in such cases there is increased destruction of red corpuscles, increased formation of bile-pigments in the liver, and thickening and stagnation of bile, with consequent absorption. In jaundice the serum has a bright yellow colour, as can be readily demonstrated, and even the tint of the blood may be appreciably altered. The bile-pigments are, however, relatively non-toxic, as considerable quantities may be injected into the blood of animals without producing serious effects. On the other hand, the salts of the bile-acids are much more important, as they have a markedly toxic action, and to their presence most of the symptoms occurring in jaundice, e.g. slowing of the pulse-rate, lassitude, somnolence, are in all probability due. In severe 'toxæmic jaundice,' however, many of the symptoms are due to the toxins which produce the jaundice. One point of interest is that in jaundice the red corpuscles have a greater resistance to dissolving agencies than in health, or in other words their isotonic point is lowered (*vide supra*)—a condition which von Limbeck explains as being due to the circumstance that the less resistant red corpuscles have been destroyed by the bile-acids. The presence of cholesterin has also been demonstrated in the blood in cases of jaundice, but it is doubtful what part it plays in the production of symptoms.

(g) *Melanæmia*.—This term, which is now less used than it was formerly, signifies the condition of the blood in malaria when it contains minute granules of black pigment which may be either free or contained within leucocytes. Similar particles may be seen in the interior of the *Hæmatozoon malariae*, and there is no doubt that the pigment is elaborated from hæmoglobin by the activity of this organism. See MALARIA.

Presence of bacteria, toxins, &c.—This subject will be treated of in connection with the individual bacterial infections, but we may here summarise a few of the chief facts. (1) Bacterial infections in which the organisms are so numerous in the circulating blood as to admit of their easy detection by means of the microscope are rare in the human subject, though they are not uncommon in certain of the lower animals. Relapsing fever is almost the only example in which the blood may be said to abound in organisms. (2) In a considerable number of diseases bacteria are present in the circulating blood, but only in comparatively small numbers. Sometimes they can be found on careful microscopical examination, e.g. in plague, influenza, anthrax, but usually only in very severe cases and often only shortly before death. Sometimes methods of cultivation are necessary in order to demonstrate their presence, and for this purpose a considerable quantity of blood removed from a vein and distributed on the surface of the culture-

medium gives the best results. By this method cultures can usually be obtained in severe pyogenic infections, ulcerative endocarditis, puerperal septicæmia, infections by the pneumococcus, &c. (see BLOOD, Examination of). (3) In a number of diseases special organisms pass by the blood-stream to various organs where they settle and multiply, but they do so in such small numbers that it is usually quite impossible to obtain them from the blood even by means of cultivation: this is the case in tuberculosis, glanders, actinomycosis, typhoid fever, and often in some of the diseases referred to in the preceding section. (4) In yet another class the organisms are practically confined to the local lesions in the tissues; if a few enter the blood-stream they are destroyed, and accordingly secondary or metastatic lesions do not occur. Cholera, tetanus, and diphtheria (at least as a rule) may be mentioned as examples of this group. In connection with the examination of the blood for bacteria and the interpretation of results obtained, it should always be borne in mind that towards the end of life, especially when death occurs slowly, the normal bacterium-free condition of the blood gradually becomes lost. In this way various bacilli and micrococci may be present in the various organs owing to an *ante-mortem* dissemination by the blood-stream.

With regard to the presence of toxins in the blood, it need only be remarked here that we have no physical or chemical means of detecting them (see TOXINS). Reference may, however, be made to various antagonistic substances (*Antikörper*) which may appear in the blood during an attack of certain diseases, as well as be developed experimentally by the injection of the corresponding bacterium or toxin. This fact is of prime importance in connection with the defence of the organism and the cure of disease. Such substances may be possessed of various properties. (a) They may be *antitoxic*, as in the case of diphtheria, in which disease it has been shown that the serum of a patient who has recovered has the property of neutralising a certain amount of diphtheria-toxin. (b) They may have a *protective* property (without being antitoxic), as shown by injecting some of the serum with the corresponding organism into an animal. In some instances, e.g. in the case of typhoid fever and cholera, this is associated with a *lysogenic* or *bacteriolytic* action, i.e. one which aids in the solution and destruction of the bacteria. (c) They may be *agglutinative*, i.e. produce clumping of the corresponding bacterium. This property—observed in the case of typhoid, cholera, Malta fever, plague, and many other infections—often appears early in the disease and constitutes the method of serum-diagnosis (see SERUM-DIAGNOSIS); it is probably closely related to the protective property, though it is not always manifested by a serum which has protective powers (see ANTITOXINS). All these substances are within certain limits specific, and are probably highly complicated in constitution, but possessing a specific chemical affinity for the substance introduced, e.g. bacterial protoplasm or toxin, as the case may be. It has been recently shown that other antagonistic sera can be produced by the injection of various organic substances; for example, by the injection of red corpuscles, leucocytes, or spermatozoa an anti-serum may be obtained which has the power of dissolving these respective bodies.

ROBERT MUIR.

M

cases, attention being drawn to the distinguishing features in any one of them. The following may be the starting points of the disease. (1) The periosteum and superficial bony layers (acute infective periostitis or osteoperiostitis). (2) The medullary cavity and inner layers (acute infective osteomyelitis or endostitis). (3) The epiphyseal lines beginning on the diaphyseal side (acute epiphysitis).

From mere continuity of tissue other parts of the bone than the point of origin may be involved. This is particularly seen in an osteomyelitis where from the medulla both epiphyseal lines may be invaded, and the whole length of the periosteum separated, causing total necrosis of the diaphysis. Again the continuity of the periosteum with the epiphyseal lines and the joint-capsule explains the frequent extension from such a starting-point to these structures. The actual point of origin may be difficult to determine in the early stage, but later may be inferred from the extent of the subsequent necrosis.

PATHOLOGY.—Rapid exudation, soon becoming purulent, takes place into the deeper layers of the periosteum, separating it from the bone, or into the medullary cavity. In either case the blood-supply to the bone is interfered with, causing necrosis, which is likely to be more extensive where the origin is osteomyelitic. The separated periosteum forms a new shell of bone, but in it certain apertures, 'cloacæ,' are usually left due to the escaping pus; through these, later on, the sequestrum may extrude. When the disease is central, septic thrombosis is very liable to occur in the veins of the bone, and emboli, being discharged into the circulation, set up pyæmia. Usually the disease is arrested at the epiphyseal junction, but in other cases extension may take place into the joint and a septic arthritis be established: this occurs particularly in the hip-joint and is due to the mutual relations of epiphysis and joint. Within the past few years it has been established by Becker, Krause, Rosenbach, and others that this disease is due to a micrococcus identical with the *Staphylococcus pyogenes aureus*. The micrococci from osteomyelitis have been injected subcutaneously and have produced local abscesses; and, on the other hand, staphylococci from abscesses &c., when injected into the circulation, produce the same results as osteomyelitis. As in other abscesses, more than one kind of organism may be present, and Fraenkel has recorded cases due to the pneumococcus.

SYMPTOMS.—One of the earliest symptoms of acute periostitis is sudden and severe pain in the affected bone, which is often attended by shivering or a rigor and intense fever. The temperature mounts quickly to 104° or 105° F. There is sweating, rapid feeble pulse, and delirium, aggravated at night. On the second or third day deep-seated swelling may be felt, somewhat indefinite at first; and the limb is swollen, hot, tense, and tender. An obscure sense of fluctuation may be distinguished at an early period; but when fluctuation becomes distinct very extensive damage will usually have taken place. After an interval varying from three to five days, the inflammation approaches the surface, the skin becomes oedematous, pits on pressure, and finally reddens and inflames. The length of interval depends on the thickness of muscles and soft parts covering the affected bone. Other things being alike in respect of pain and

amount of fever, the longer the delay in the appearance of external swelling, the greater the probability that the medulla with the adjacent bone is the first and chief tissue engaged, the inflammation having reached the periosteum secondarily; while the early appearance of swelling and fluctuation externally suggests that the inflammation is chiefly periosteal. Septicæmia or pyæmia may supervene.

DIAGNOSIS.—This disease may be obscure at the commencement, and its nature overlooked. It has often been mistaken for acute rheumatism, on account of the swollen joints; for phlegmonous erysipelas; for acute cellulitis, or for typhoid fever. The only malady which acute periostitis really resembles is an idiopathic inflammation of the deep-seated cellular tissue in a limb. This disease is rare. When we observe the chain of symptoms above described in a young person, we may safely assume the presence of an acute osteoperiostitis.

COURSE AND TERMINATIONS.—The disease almost invariably terminates in suppuration and necrosis; resolution happens rarely, but necrosis is not inevitable, even after suppuration. In a few cases, especially in young children, if the matter be speedily evacuated, the abscess collapses, the periosteum reunites with the bone, and no necrosis takes place. This result is unfortunately quite exceptional. Resolution without suppuration may be the case where more than one bone has been involved, the pain and tenderness in those later attacked being succeeded only by thickening.

PROGNOSIS.—This must be founded on the extent of the necrosis; whether blood-poisoning has taken place; and whether the adjacent joints are implicated in the disease. Cure cannot take place until the dead bone is cast off or removed, and this is often long delayed. The usefulness of a limb may be permanently impaired by the disease, or it may require amputation; or the patient may lose his life from the exhaustion of the discharge or some intercurrent malady. On the other hand, the use of the limb, and the health of the patient, may become completely re-established.

TREATMENT.—Early and energetic treatment is of the greatest importance, as it affords the best prospect of averting the disastrous consequences of acute periostitis, but in hospital practice the cases are rarely seen sufficiently early. In the first stage the limb should be elevated, and cold compresses applied. As soon as the nature of the affection is suspected free incisions down to the bone, so as to divide the periosteum, are indicated, even before there is clear evidence that pus is formed. They relieve pain and tension; and, by permitting the timely escape of pus as soon as it is formed, the amount of periosteal separation, and consequently of necrosis, is limited. It is the more important to make an early incision, because evidence of fluctuation is at first by no means easy to make out; and an incision down to the bone should be made in the centre of the inflamed area in all cases of doubt. Antiseptic precautions should always be taken. Sometimes the abscess-cavity does not readily collapse owing to its walls being stiff and infiltrated, and its contents may become septic, thus greatly increasing the patient's risks. If there be synovial effusion into a neighbouring joint, it should be kept at rest by means of a splint or a fixed bandage, but on the slightest suspicion of the nature of the effusion it may be aspirated for diagnostic purposes. As the acute symptoms subside, the

abscess-cavity contracts, one or more sinuses remain, and the dead bone begins to separate. See NECROSIS, page 167.

Where an epiphysis is engaged in the disease the case is more urgent; the fever runs higher, the suppuration is greater, and the degree of joint-implication more intense, proceeding in extreme cases to suppurative inflammation and destruction of the articulation. In such involvement of the joint free incision and drainage will be needed. The affected limb should always be supported on a splint. (Edema of the limb often indicates a deep-seated phlebitis, the precursor of septic poisoning. Under these circumstances, amputation is often the only resource. It is imperative to amputate where there is extensive bone-destruction, and the symptoms indicate commencing pyæmia; or where, with the death of a large portion of the shaft, one or both of the neighbouring joints may have become gravely implicated, and great suffering and loss of strength forbid us to temporise. It is precisely in these cases, however, where the diaphysis has become necrosed up to the epiphyseal junction, that good results are attainable by the immediate extraction of the dead bone. The part of the shaft which joins the epiphysis becomes rapidly detached and loose, and may be readily separated and removed, while the portion beyond the limit of the necrosis in the other direction can be divided with a chain-saw. It is difficult, however, in the early stage to diagnose the extent of the necrosis. Where the joints both above and below are involved, amputation is usually necessary.)

(b) *Chronic periostitis*.—This disease is usually due to some diathetic cause, but may result from injury, or from some continuous pressure or source of irritation. It is most frequent on the superficial parts of the skeleton, as the tibia, clavicle, skull, and ribs, but may affect any bone; and it is often observed at the origin or insertion of muscles. When the disease arises from a general cause, such as syphilis, many parts of the skeleton are affected; when from a local one, usually only one.

SYMPTOMS.—Chronic periostitis often takes the form of what is called a *node*—a tender, more or less painful, rounded or oval swelling; at first tense and hard, afterwards softer or even fluctuating. The pain is more severe at the outset, from the tension of the parts involved, and is generally worse at night. Subsequently the swelling becomes indolent, and painless, unless it is pressed upon; and the effused matter may become organised first into fibrous tissue and then into bone. Nodes are due to a localised inflammation, forming a well-marked projection on the bone, which may undergo resolution, suppurate, or ossify, according to circumstances.

PROGNOSIS.—In chronic periostitis this is usually favourable. Under the influence of early and suitable treatment, the inflammatory products are completely absorbed, and the bone resumes its natural shape. If the chronic inflammation of the periosteum be permitted to proceed unchecked, a deposit of new osseous lamellæ usually takes place on the surface of the affected bone, giving rise to permanent thickenings, or even to osteophytic growths. These are composed of light porous bone, with a rough surface. The skeleton of a syphilitic subject will often present numerous thickenings of this nature. On making a section of the bone, it is easy to see that the new bone is superimposed upon the old, and is formed by the periosteum.

TREATMENT.—When due to a local cause, the swelling will often spontaneously subside with removal of the cause and rest to the part; but in obstinate cases iodide of potassium internally, and iodine-ointment or blistering externally, may be required. If the subject be unhealthy, or if the original injury be considerable, suppuration may take place, when the treatment will be that of an inflammatory abscess. *Syphilitic nodes*, which are a very common expression of chronic periostitis, yield rapidly to the influence of iodide of potassium; and this in some cases may usefully be combined with a mercurial course. Blistering or friction externally is hurtful in such cases. Syphilitic nodes are not at first prone to suppuration, and even when they become soft and fluctuating, and the skin reddens over them, they should not be mistaken for abscesses, as they do not require incision, and will readily be absorbed under suitable treatment.

Periostitis after fevers.—A peculiar form of periostitis is occasionally observed as a sequel of specific fevers, especially typhoid fever. It is due to a mild infection from some ulceration, such as Peyer's patches in typhoid fever or the throat in scarlet fever. In typhoid fever it occurs during convalescence, and without general symptoms. It takes the form of hot, painful, and tender nodes, frequently symmetrical, and often placed on the tibia; the disease is also found on the ribs and other bones. It may be associated with necrosis, but if so the extent of the dead bone is small in proportion to the inflamed area of periosteum. The general health is not seriously affected by the periostitis, and the disease is amenable to treatment by iodide of potassium, combined with iodide of iron.

(B) **Osteitis.**—Osteitis is an inflammation chiefly affecting the bone-substance. It may be either *acute* or *chronic*.

(a) *Acute osteitis* is neither clinically nor pathologically to be distinguished from acute osteomyelitis or endosteitis. See OSTEOMYELITIS, p. 166.

(b) *Chronic osteitis* is a disease beginning in the bone, in which from first to last the chief changes occur, the periosteum being secondarily engaged. This affection may result from injury, or be excited by exposure to cold; but it is often associated with syphilis, tuberculosis, gout, or rheumatism, the first being the most frequent cause. It may occur in any part of the skeleton; the chief changes, when produced by syphilis, occur in the shafts of the long bones. They consist mainly of hypertrophy, and the bone is ultimately increased in thickness, in length, and generally in density: its interior is often transformed into sclerosed bone-tissue, and the medullary cavity is obliterated. Another form, associated with the strumous diathesis, is generally seated in the joint-ends of the long bones, and in the spongy bones. It is prone to end in suppuration, accompanied by either caries or necrosis, or may terminate in the condition known as *osteoporosis* or *rarefying osteitis*. The gouty and rheumatic forms are associated with evidence of the presence of either of these diatheses.

PATHOLOGY.—Increased vascularity first takes place, the Haversian canals enlarge, the canaliculi disappear, the cancelli, containing the inflammatory products, enlarge, and the earthy matter diminishes. Hence the inflamed bone softens, and, if macerated at this stage, will be found comparatively light and porous. When the inflammation affects the superficial laminae of the bone, the peri-

osteum becomes thick and vascular; if the deeper parts are involved, similar changes will occur in the endosteum. The porous condition of the bone may become permanent, when the condition is called *osteoporosis*, the result of so-called rarefying osteitis; or the granulations become transformed into new bone, and the cancellous structure is filled with osseous deposit, so that the whole of the inflamed area becomes very dense, and is then said to be sclerosed; or the inflammatory process may terminate in suppuration, followed by caries or necrosis; or an abscess may form in the interior of the bone, and be either diffused or circumscribed.

SYMPTOMS.—These are insidious, very obscure at the outset, and may be mistaken for those of chronic rheumatism, or simple periostitis. They consist chiefly in aching, gnawing pain in the affected bone, with characteristic remissions and nocturnal exacerbations. The bone is tender on pressure, and feels increased in bulk at first, from the infiltration of the immediately surrounding soft tissues; subsequently the bone itself enlarges. There is often increase of heat in the limb. The progress is chronic. If unchecked by treatment, chronic osteitis may give rise to considerable deformity.

TREATMENT.—Treatment should be directed to the cause of the disease. If this be syphilis, antisyphilitic treatment will be followed by good results; even in chronic bone-inflammation not dependent on syphilis, iodide of potassium is often of great service. Local counter-irritation may also be employed. Often the cause cannot be made out, and if iodide of potassium fail in producing an effect we must fall back on general treatment. In the early subacute stage, rest, with elevation of the affected part, is very desirable. Warm fomentations, followed by iced compresses, relieve the suffering. If there be much pain and tension, leeches should be applied. Puncturing the tissues down to the inflamed bone, with a tenotomy-knife or fine bistoury, relieves the tense periosteum, and allows extravasation beneath it to escape, so that the pain promptly abates.

(C) **Osteomyelitis.**—This is an inflammation of the medullary cavity and the endosteum. Like osteitis it may be either acute or chronic.

(a) *Acute simple osteomyelitis* will occur in a varying degree in any injury to the medulla which remains aseptic, as in simple or compound fractures or after amputations.

Acute infective osteomyelitis has been referred to before under acute infective periostitis, and here the infection had been derived from the blood. Any open wound, whether due to a compound fracture or amputation, where the medullary cavity has been opened, may become contaminated with septic products, and an *acute septic osteomyelitis* develop. This condition is very liable to be associated with septic thrombosis and pyæmia. The appearance of the wound will change and there will be some swelling of soft parts and tenderness about the bone. The discharge alters and may be offensive. With this there will be some fever and probably a rigor. On opening up an amputation stump which has become septic the periosteum will be found separated from the bone, which is discoloured, and the medulla will have lost its normal vascularity. The prognosis in these cases is generally bad.

TREATMENT.—Directly such a complication is suspected the wound must be most thoroughly ex-

amined. If, after cleansing the wound well and getting rid of all tension, the medulla near the surface seems vascular, we may temporise, provided that the constitutional symptoms allow of it. But as this is rarely the case amputation is usually required. To get above the diseased medulla it is generally held that no operation is of any avail unless the whole of the diseased bone is removed. In dealing with the upper end of the femur the medulla has been scraped out and packed, and by some this method has been extended to other bones instead of resorting to a high amputation.

(b) *Chronic osteomyelitis* is an obscure affection not to be distinguished either clinically or pathologically from chronic osteitis. It may terminate in sclerosis, or in the formation of an abscess. See **CHRONIC OSTEITIS**, p. 165.

2. **Abscess.**—This is a term usually applied to a limited suppuration in the bone, unattended by any marked necrosis. Young adults are most prone to the disease, or boys about the age of puberty; it is very rare in women. It is the result of a chronic inflammation of bone, which may be associated with some injury or due to tuberculosis. This affection is most frequently met with in the upper and lower extremities of the tibia, just external to the epiphyseal cartilage, less frequently in the ends of the femur, only occasionally in other bones, and very seldom in the compact tissue anywhere.

SYMPTOMS.—A circumscribed, slightly elevated, very tender and painful swelling may be discovered on the surface of the bone. This is due to a local periostitis with new bone-deposit. In old-standing cases the bone is often half an inch or an inch longer than its fellow, by reason of the chronic hyperæmia and consequent increase of activity of growth at the epiphysis. The skin and superficial parts are unchanged at first, or there may be but trifling subcutaneous œdema. There is often slight local increase of temperature. The pain, aggravated on deep pressure at the central point, is often intolerable. It is intermittent at first, but generally worse at night. After a time it becomes continuous, and deprives the patient of all rest, owing to its severity. The abscess may persist with little change for months or years. The symptoms generally resemble those of osteitis, from which at the outset it is difficult to distinguish this affection. When the abscess approaches the periosteal surface, the soft parts become involved, and there will be slight redness and œdema of the skin. More rarely the pus makes its way into the adjacent articulation, in which it sets up destructive inflammation; but usually the joints are free from implication. The subjects of the disorder have often suffered from antecedent bone-disease. Evidence of this should be looked for, as giving a clue to the diagnosis.

TREATMENT.—Spontaneous cure cannot occur: even if the abscess discharge itself, a permanent fistula will usually remain. It is necessary to lay the abscess-cavity freely open. A crucial incision must be made through the soft parts, down to the bone, at the most tender and prominent point, and a disc of bone removed by the bone-trephine—an instrument without a shoulder, about half an inch in diameter. The sudden loss of resistance indicates the piercing of the abscess-cavity. The layer of granulation-tissue lining its interior should not be interfered with, but the cavity simply washed.

out. The pus is often foul, and greenish in colour. The wound should be dressed antiseptically; granulations presently fill it, which are subsequently transformed into a fibrous cicatrix. Immediate and permanent relief follows the operation. If the abscess is missed, the trephine may be re-applied, or drill-punctures made in the most likely directions in the adjacent bone, in order to discover the pus. Sometimes an error of diagnosis is committed, and the symptoms are found to arise from chronic osteitis, without suppuration. The operation, nevertheless, affords relief in these cases also. When there is doubt, a preliminary course of iodide of potassium will often remove it.

3. **Caries.**—The term caries does not express any definite disease, although so frequently used as a synonym of tuberculosis of bone, but only a pathological state which may be produced by several causes. It has been spoken of as ‘ulceration of bone’ or ‘molecular death.’ Its essential feature is a rarefying osteitis which involves usually the cancellous tissue, the bony framework gradually disappearing in front of the granulation-tissue.

Many forms of caries have been described. ‘Simple caries’ may be met with in its most typical form (1) in an acute septic arthritis, where, after the destruction of the cartilage, the ends of the bone become involved; or (2) on the surface of a bone where the soft parts are destroyed. ‘Caries fungosa,’ ‘caries necrotica,’ and ‘caries sicca’ are variations in the tubercular process, and will be referred to under that heading (*vide infra*).

4. **Necrosis.**—The complete arrest of nutrition in a portion of bone from any cause is followed by the death or necrosis of the bone, and by a series of inflammatory changes in the adjacent parts, which result in the complete separation of the dead from the living tissue. It is a common result of the acute inflammation of bone which is invariably connected with some septic or infective cause.

ÆTIOLOGY.—Necrosis is most frequently the result of acute bone-inflammation or severe injury, as after amputation, compound fracture, or contusion. It is especially prone to happen in the compact tissue, but it also occurs in the spongy structure, as the ends of the long bones, or the tarsus and carpus, where it is usually associated with more chronic forms of inflammation, and is more limited, as in necrotic caries. The peculiar nature of the blood-supply to bone, and the facility with which it may be interfered with or arrested under the pressure of inflammatory exudation, go far to explain the frequency of necrosis as a result of bone-inflammation. Acute suppurative osteoperiostitis or osteomyelitis rarely terminates without necrosis. Whether the dead bone will be in the superficial or the deep lamellæ, or include the whole thickness, depends on the seat of the inflammation, and on the extent to which the periosteum and endosteum are respectively implicated. The long-continued action of crude phosphorus, as observed in match-makers, and also of mercury, may induce necrosis. Syphilis is a frequent cause of necrosis, through its tendency to produce chronic osteoperiostitis, the sclerosed bone thus originated being afterwards prone to necrose. It is not an uncommon sequel during convalescence from some eruptive and continued fevers. After scarlatina, osteoperiostitis, followed by necrosis, is by no means rare, although affections of the joints are

more common. It is probable that many cases of necrosis occurring in childhood are connected with an antecedent attack of scarlet fever, e.g. necrosis of the petrous portion of the temporal bone as a consequence of otitis. Arterial thrombosis and embolism are occasional sequelæ of typhus, and may produce a local gangrene, not only of the soft parts, but of bone. This is, however, more frequent in connection with typhoid fever. In endocarditis the nutrient artery of a bone has been found obliterated by an embolus, thus producing necrosis.

PATHOLOGY.—After the death of a portion of bone, the living tissue, in immediate contact with the dead, becomes inflamed. The Haversian canals and canaliculi become distended with migratory cells; the leucocytes multiply, and by degrees consume the hard substance of the bone; the trabeculæ are absorbed or eaten away; loops of capillaries form from the pre-existing vessels: a granulating surface, in fact, is formed in the layer of living bone, surrounding or in contact with the dead, in a manner precisely similar to what takes place in the soft parts when a slough is being detached. The periosteum separates from the bone, and becomes thick and vascular, while the osseous surface beneath is smooth and white, like macerated bone. In cases of syphilitic necrosis, as well as in that resulting from phosphorus, the surface is rough from antecedent periosteal deposit, and in the former the interior may also be sclerosed. How the osseous trabeculæ are dissolved or disintegrated at the surface of separation, so as to loosen the dead bone, is not certain. Probably the granulation-tissue that forms from the living bone possesses phagocytic properties, and thus disposes of the calcareous particles. The pus that is formed has a mechanical influence, while according to one theory lactic acid is produced, which transforms the insoluble into soluble salts of lime. While this loosening process is going on, new bone, formed chiefly from the periosteum, which becomes thick and vascular, is being deposited, constantly becoming thicker, and with one or more openings in it for the escape of pus, called *cloaca*, so that eventually the dead portion becomes completely invaginated, and is named, from its position, a *sequestrum*. This sequestration of the dead bone is not invariable. For instance, in the spongy bones, the bones of the skull, and the upper jaw, or where from any cause the periosteum has been destroyed, no sheath of new bone will be formed. Necrosis very rarely takes place without suppuration; when this does happen the nature of the case is very obscure. It has been aptly called ‘quiet’ necrosis. Occasionally nearly the whole shaft of a long bone has been found necrosed, and after an interval of months, or even years, no suppuration may have taken place. Such forms of necrosis are usually central and limited in extent. They may very closely simulate malignant disease, and often cannot be relieved or even recognised save after amputation. A chronic osteitis, followed by hypertrophy and sclerosis of the bone, is the most common antecedent condition of this form of necrosis.

TREATMENT.—The changes already described, which separate the dead bone from the living, do not cause its expulsion from the body. On the contrary, they shut it up, like a kernel within its shell, and nothing so imperatively demands surgical interference as the presence of necrosed bone.

acts as a foreign body, is a constant source of risk to the patient, and should be removed as soon as practicable. Its continued presence excites the periosteum to further formation of bone, so that the invaginating sheath becomes of great thickness in old-standing cases. The period at which an operation is usually undertaken is when the sequestrum has become loose, and the time required for this purpose varies with the extent of the necrosis. In the actively growing bones of the young, especially when the sequestrum involves the epiphyseal junction, the process of separation is accomplished more quickly than in the adult. Roughly estimated, a period of from three to six months might be named as that within which loosening of the sequestrum usually occurs. Beyond the latter term an effort to extract the dead bone should not be delayed, even if it cannot be felt to be loose. Among other risks involved by delay may be that of amyloid degeneration of the viscera, principally the liver, kidneys, and spleen, which are subject to this change as the consequence of long-continued discharge from bone-disease. In order to remove a sequestrum, a director should first be introduced through a cloaca as a guide, and the soft parts sufficiently divided. An adequately large opening must now be made in the encasing sheath of new bone with the chisel, trephine, small saw, or cutting-forceps, and the dead bone extracted, either in one or several pieces, as may be the more convenient. The operation may prove difficult on account of great thickness of the soft parts, or of the sequestral envelope, or because the sequestrum itself is extensive. After the removal of the dead bone the cavity fills with granulations, which subsequently ossify, and the soft parts cicatrise. When the loss of bone-substance is very large the reparative process has been much facilitated by the implantation of small pieces of bone from a freshly killed rabbit. Finally the sequestral envelope of new bone is partly absorbed, partly consolidated, just as the redundant callus is after fracture, and the bone tends more or less to resume its normal size and shape.

5. Diseases of Infective Origin (*granulomatosa*).—(a) Tuberculosis.—A very large majority of the cases of chronic bone-disease are the result of tubercular infection. This form of local tuberculosis is most frequent in young subjects, but it may arise after middle life and form one of the lesions designated as 'senile tuberculosis.' The parts usually involved are (1) the cancellous tissue of the small bones of the carpus and tarsus, (2) that in close relation with the epiphyseal cartilages at the end of the long bones, or (3) that of the vertebrae. The small long bones of the hand and foot are frequent sites, but here the lesion is mostly an osteomyelitis. Involvement of the shaft of the long bones, although it occurs, is rare.

PATHOLOGY.—The disease of the bone is a chronic inflammation causing a rarefying osteitis or 'caries,' but occurring secondarily to the formation and degeneration of 'tubercles.' This invasion of the healthy bone by the granulation-tissue is progressive. True pus is not present unless there is an additional infection from pyogenic bacteria. Certain clinical terms are associated with the starting-point of the disease and with the pathological changes. The frequent origin beneath the articular cartilage of a joint accounts for the term 'subarticular caries.' The usual sequel here is absorption and perforation of this cartilage with involvement of the joint-cavity,

the granulations frequently being exuberant and sprouting (*caries fungosa*). During the invasion of the bone by the granulation-tissue certain areas of rarefied bone may be isolated before they have become completely absorbed. Should degenerative changes now occur in these granulation-barriers, these portions of bone are cut off from their blood-supply and appear as small sequestra (*caries necrotica*). If the products of degeneration are occluded in the surrounding bone a *chronic abscess* of bone is formed. A more favourable course may be run when the bone is progressively absorbed without any such degenerative changes in the granulation-tissue, the latter becoming organised and the neighbouring bone often sclerosed (*caries sicca*), a process most frequently met with at the upper end of the humerus. Miliary tuberculosis may be met with, particularly in the medulla, but it only occurs as a part of a general tuberculosis, has no clinical significance, and is very rare.

SYMPTOMS.—Of the general process there are no special symptoms beyond those related to the part involved. The condition of health varies considerably, but a history of any hereditary tendency to tuberculosis aids in making a diagnosis. Pain and tenderness with restriction of normal range of movement may first attract attention; later on this is followed by swelling. Often a chronic abscess or some other complication may be the first sign. As the softened products make their way to the surface the covering tissues become gradually thinned, till at last the skin gives way. In this way a *sinus* is formed leading down to the diseased area, and lined by weak granulations discharging a thin watery fluid; the skin forming the margin of the opening is often irregular and undermined.

TREATMENT.—In cases of this kind general tonic treatment becomes of the greatest importance. Rest must be given to the affected part, and exercise to the body generally, combined with fresh air both day and night, and simple nourishing food. An operation becomes necessary when softening has occurred, the degenerated products being removed by incision and scraping. When the bone is extensively diseased, it must either be excised, or the part amputated. The presence of the tubercular diathesis does not forbid an operation, the local source of irritation and drain upon the system being thus removed, and a healthy traumatic surface substituted for one infiltrated with inflammatory products. The removal of the local disorder often proves a comfort to the patient; increases his chance of regaining health and strength; and diminishes the liability to dissemination.

(b) **Syphilis.**—In both the acquired and inherited disease lesions are met with which are practically of the same nature. In *acquired syphilis*, during the secondary period, a local periostitis, forming a node, is most frequent. There may be symmetry in the lesions, or more rarely many nodes may be studded over several bones. The local changes are, as a rule, very limited and, under the use of appropriate treatment, speedily disappear, leaving little or no trace behind. It is a different matter, however, with the lesions in the late stage. Here the changes are much more marked and the inflammatory process may involve periosteum, bone, or medullary cavity, and be limited or diffuse. The production of new bone is a feature which causes great thickening and irregularity of the surface, and in the bone itself reduction in size of the Haversian canals, as

well as increased density. The osteo-sclerosis may be so intense as to cause necrosis, and the sequestrum so formed, as a rule, separates very tardily. Where the changes are limited a gumma is formed, which may soften or resolve.

In *Inherited Syphilis* the commonest early change is inflammation about the epiphysis associated with fluid in the neighbouring joint, and a varying amount of periostitis up the diaphysis. Later on much the same changes are found as in the acquired disease, but the lesions are frequently symmetrical. The treatment indicated is that for syphilis in general, but whether the bone-lesions occur in the early or later stages, the nocturnal pain, which is distressing and constant, may be relieved by iodide of potassium.

(c) **Actinomycosis.**—This disease arises from the transmission to man of a vegetable parasite found usually in the bovine race. Its development in bone mainly occurs in the jaws (generally the lower), in which it causes great swelling. The jaw is distended by a mass of material chiefly inflammatory, consisting of a fibrous basis which is riddled with tracts occupied by the fungus. When suppuration occurs, the abscess-cavity presents the appearance of a mesh-work. See ACTINOMYCOSIS.

6. **Hypertrophy.**—True hypertrophy means an increased size of the bone, which still preserves its normal shape and structure. Apart from inflammation hypertrophy is rare. The conditions may be met with in association with increased muscular development or in a congenitally hypertrophied limb. Hypertrophy of the fibula has been observed, owing to increased weight thrown upon it, in cases of ununited fracture of the tibia.

7. **Atrophy.**—This is met with as a constant condition in old age, leading to enlargement of the medullary cavity at the expense of the cortex. Disuse and abnormal pressure are also frequent causes. The thinning of the bone gives rise to lessened resistance, so that fractures may occur spontaneously, or from very slight causes.

8. **Disorders of normal ossification.**—In the first place the arrangement of the skeleton may be followed, but yet be of altered proportions, as in cases of true dwarfism or gigantism; the former condition must be differentiated from that due to rickets or achondroplasia, the latter from acromegaly. Departures from the normal type are met with in suppression or addition of parts, generally of congenital origin. Various deformities occur from fractures, both intra-uterine and subsequent to birth.

The following two diseases exhibit metaplastic changes in the skeleton of either generalised or limited distribution; they are not dependent on any infective process and are generally associated with deformity.

(a) *Rickets.*—See RICKETS.

(b) *Achondroplasia or Chondrodystrophia fetalis.*—See ACHONDROPLASIA.

9. **Diseases associated with degenerative changes in normally formed bone.**—The pathological factor here is metaplasia of the normal bone-structure into another form of connective tissue, and is well illustrated in osteomalacia and osteitis deformans. Both of these diseases are non-inflammatory, and in them the architecture of the bone is greatly altered; the bones are softened and bend, causing various deformities. In osteomalacia there is a disappearance of the normal structure, and its place is taken by similar material to that occupying

the central canal, the change being usually eccentric, whereas in osteitis deformans the medullary tissue and normal bone are replaced by a spongy form of bone. Cases showing transitions between these extremes have been described, and in young subjects the victims of fragilitas ossium, apart from rickets, there is some such bony change. Another point to note is that in both osteomalacia and osteitis deformans the metaplasia may be accompanied by tumour-formation.

(a) *Osteomalacia or Mollities ossium.*—See MOLLITIES OSSIIUM.

(b) *Osteitis Deformans.*—This affection is one chiefly of elderly men. In a few cases only a single bone may become thickened and bent, but when many bones are involved a very characteristic clinical picture is produced. The head is enlarged and, owing to the general curvature of the spine, projects forward almost on to the sternum. The legs are bowed, giving the skeleton a simian type. The involvement of individual bones of the limbs varies, but there is a rough symmetry to be noticed. The progress of the disease is very slow, death generally resulting from some chest-affection, which is very prone to occur from the fixation of the ribs.

The bones on examination show great thickening with replacement of the compact tissue by porous bone, which also fills up the medullary cavity. There is no special treatment to be advocated for this slowly progressive disease.

(c) *Acromegaly.*—See ACROMEGALY.

(d) *Leontiasis ossea.*—The bones of the face and cranial vault are the sites of bony masses which get progressively larger, lead to marked deformity, and involve nerves, particularly the optic nerves, causing blindness. This hyperostosis implicates the entire bone, and more or less symmetry will be noted.

(e) *Anakhre.*—See ANAKHRE.

10. **Tumours of Bone.**—These are mainly of the connective-tissue type, either embryonic or of a more highly developed character. Primary epithelial growth of bone has been described, but it is a pathological curiosity and may be looked on with some suspicion; secondary epithelial tumours are not infrequent, associated especially with carcinoma of the mamma. Osteomata, chondromata, fibromata, and sarcomata, may occur primarily in bone. See TUMOURS.

Sarcomata.—These may be divided into those of central and periosteal origin.

(i) *Central.*—It is a debatable point whether the so-called *myeloid sarcomata* or *myelomata* should find a place under Sarcomata. These giant-celled tumours occur in the jaws and at the ends of the long bones, especially the tibia, lower end of femur, and radius. They are soft and absorb the bone, so that after a while there is only a bony shell produced by the expanded periosteum, which gives the egg-shell crackling. Cystic changes frequently occur, and sometimes they pulsate. They are considered to be non-malignant, and on these grounds local removal is recommended as far as it can be done to leave a useful limb; if recurrence occur, it is from admixture of other sarcomatous elements.

The central sarcomata may be spindle-celled or round-celled, especially the latter. Clinically, they are rounded and may give 'egg-shell' crackling; spontaneous fracture frequently occurs. Pain may precede any swelling. These soft tumours are very vascular and often pulsate: the ill-supported

vessel-walls frequently give way, causing hæmorrhage into the tumour.

(ii) The *periosteal* sarcomata may be spindle-celled or round-celled, more frequently the former. The growth on the shaft of a long bone shelves down to the shaft, giving it a fusiform shape; it is often irregular on its surface, and hard from the amount of ossification which occurs. Pain is not so marked, and spontaneous fracture is not so likely to occur, as in central growths: unfortunately, however, their standard of malignancy seems higher and they tend to recur locally. The treatment of these true sarcomata is to amputate well above the disease as soon as possible.

Osteo-aneurysm is a term that has been applied to certain pulsating bone-tumours which are usually central sarcomata. Berger has recently suggested that many of these cases are endotheliomata of bone which pulsate, are very malignant, and are very prone to be rapidly generalised. The secondary growths all show the same characteristic pulsation.

Cysts.—Hydatids are rarely met with. The commonest cystic bone-tumours are on the jaws either from retained teeth, *dentigerous cysts* or the *dental cyst* met with in association with decayed stumps.

WILLIAM MACCORMAC.

HENRY BETHAM ROBINSON.

BORBORYGMI (βορβορύγμ, I rumble).—Rumbling sounds produced in the abdomen by the movements of gas within the bowels or stomach. See FLATULENCE.

BORDIGHERA, on the Italian Riviera.—A suitable winter residence for patients suffering from some forms of renal and of chest-disease. The climate is warm and dry. See CLIMATE, Treatment of Disease by.

BORMIO, in Italy.—Thermal waters. See MINERAL WATERS.

BOTHRIOCEPHALUS (βόθριον, a pit; and κεφαλή, the head).—A genus of cestode entozoa, characterised by the possession of two pits, or depressions, one on each side of the head, in place of the four sucking-discs usually present in tapeworms. See ENTOZOA.

BOTULISM (*L. botulus*, sausage).—A term at first applied generally to sausage-poisoning, but now generally limited to a set of symptoms, including dryness of the mouth, difficulty in swallowing, dilatation of the pupils, and ptosis, due to the action of the toxins produced by the growth of the *Bacillus botulinus* in meat.

BOURBONNE-LES-BAINS, in France.—Common salt waters. See MINERAL WATERS.

BOURBOULE, LA, in France.—Thermal alkaline and arsenical waters. See MINERAL WATERS.

BOURNEMOUTH, in Hampshire.—A suitable winter residence for patients suffering from certain forms of chest-disease. The climate is mild and slightly humid. See CLIMATE, Treatment of Disease by.

BOWELS, Diseases of.—See INTESTINES.

BRACHIAL PLEXUS, Lesions of.—Paralysis due to lesions of the brachial plexus differs according

to whether the whole plexus is damaged or only some of the roots of which it is composed. When the whole plexus is damaged, as from violent traction on the arm or after reduction of a dislocated shoulder, there is paralysis of all the muscles of the upper limb with complete anaesthesia up to the shoulder.

When only certain of the spinal roots which form the plexus are injured, the resulting paralysis is that of the muscles which receive their nerve-supply from the particular root or roots affected. The most common association of muscles involved is that of the deltoid, biceps, brachialis anticus, and supinator longus. Erb showed that this combination of muscles was supplied by the 6th cervical spinal root, and discovered a point in the posterior triangle of the neck situated behind the posterior border of the sterno-mastoid and 2·3 centimetres above the middle of the clavicle, stimulation of which by the faradic current caused contraction of these muscles only. This combination of paralysed muscles has been called *Erb's paralysis*. Since then, anatomical, clinical, and experimental observations have shown that this root is more probably the 5th and not the 6th cervical. In addition to the deltoid, biceps, brachialis anticus, and supinator longus, the supra- and infra-spinati and sometimes the supinator brevis are also paralysed.

This combination may be due to a rheumatic neuritis, or to pressure from a tumour, but the most common cause is a fall from a height on to the side of the head and the shoulder of the same side, forcing them apart so that the brachial plexus is violently stretched, and the upper roots, the 4th and 5th cervical, being attached furthest away from the angle formed by the upper limb and the spine, are more violently stretched than the lower roots which are below the level of the clavicle. The paralysis is occasionally caused by direct pressure on the 5th cervical root, as in a case published by the writer, of a woman who went to sleep with her neck resting on the sharp edge of a table, and on waking up had a tender spot over the posterior border of the sterno-mastoid four centimetres above the middle of the clavicle corresponding to the part pressed upon. In addition to paralysis of the deltoid, supra- and infra-spinati, biceps, brachialis anticus, supinators longus and brevis, and teres minor, she had a feeling of numbness with anaesthesia of the thumb and the radial border of the forearm and arm up to the shoulder. Another form in new-born children is known as *Obstetrical paralysis*. It occurs after pressure of the forceps on the brachial plexus, or in breech presentations from severe traction on the shoulder. At birth one arm is noticed to be in the typical position due to paralysis of the same muscles as in Erb's paralysis.

In Erb's paralysis as in the obstetrical paralysis the loss of power occurs immediately after the injury, and the position of the upper limb is very characteristic. The humerus hangs straight down, and when lifted up and let go it drops like a flail; it is adducted to the trunk, and rotated inwards; the elbow is kept extended and the forearm is pronated. The patient is unable to advance the humerus or to abduct it away from the chest wall, and in attempting to do this the shoulder is elevated and the scapula is rotated with the inferior angle forwards, but no abduction occurs. The patient cannot flex the elbow, and supination of the forearm is lost or very weak. Flexion and extension of the wrist and fingers, and all the movements of the thumb and separation

of the fingers by the interossei are well performed. In Erb's paralysis sharp pains are felt along the shoulder and the outer border of the arm and the radial border of the forearm down to the thumb, and anæsthesia is found on the outer half of the arm and the radial half of the forearm involving sometimes the thumb.

If the lesion of the brachial plexus is more extensive, other muscles in addition to those given above may be involved, as in two cases published by the writer: in one, besides the supra- and infraspinati, deltoid, biceps, and supinator longus, the triceps, pectoralis major, latissimus dorsi, pronator teres, and flexor carpi radialis were almost completely paralysed; while in the other, the extensors of the wrist and digits were also affected. These cases were due probably to the 6th and 7th roots being also involved. Cases in which the triceps, latissimus dorsi, and lower half of the pectoralis major are involved without the deltoid-biceps group are not usually met with, though they might occur.

In Erb's paralysis the muscles of the wrist and digits escape entirely, but a group has been observed in which the converse occurs, and these muscles are involved while the deltoid-biceps group escape. These cases are not produced by falls on to the head and shoulder, but by direct injury, as gunshot-wounds below the clavicle involving the 1st dorsal root and perhaps the 8th cervical root of the plexus. The thenar and hypothenar muscles and the interossei are paralysed, so that it is not possible to abduct and adduct the thumb properly or separate the fingers or to abduct the little finger; the little and ring-fingers suffer more than the other fingers and thumb. Owing to paralysis of the interossei the fingers become 'clawed.' Anæsthesia and sharp pains occur in the 3rd and 4th fingers, along the ulnar border of the forearm, and sometimes along the inner border of the humerus up to the axilla. Ocular troubles are noticed in these cases, and consist in inequality of the pupils, especially marked when the eyes are shaded. Moreover it is noted that the pupil on the same side as the paralysis, though it contracts to light, does not dilate fully when shaded; also the upper eyelid falls slightly and the palpebral fissure is smaller on the paralysed side. These changes are due to paralysis of the dilator fibres of the iris and of the fibres of Müller's muscle, which come from the spinal cord through the sympathetic and have been found in the dog to leave the cord by the 1st dorsal root.

In all these cases of paralysis the affected muscles waste, and give the typical reaction of degeneration (see ELECTRICITY IN MEDICINE). If the roots are ruptured and do not join again, the muscles in time lose all their excitability and do not then recover. The *diagnosis* has to be made from other forms of neuritis, by the characteristic combination of the paralysed muscles; and from progressive muscular atrophy, by the sudden onset and the presence of anæsthesia. The *prognosis* differs according to the cause and the degree of the injury. In cases of falls on to the head and shoulder recovery would depend on whether the roots of the plexus were only stretched or actually ruptured, but even after slight pressure, as in the case of the woman mentioned above, it was two or three months before the muscles recovered, and in severe cases it may be a year or more; but as long as the muscles react to the constant current there is a chance that they may recover. The obstetrical cases as a rule recover,

but not invariably. The *treatment* consists in keeping up the nutrition of the muscles by massage and by a gentle constant current, using only just enough to cause a contraction of the muscles. In cases of paralysis due to a tumour growing on, or pressing on, the roots of the brachial plexus, removal of the tumour and suturing the ends of the nerves might be required.

C. E. BEEVOR.

BRADYCARDIA.—An infrequent pulse (below 60), corresponding to infrequent heart-beat. The term is not properly applied to cases in which a frequently or normally beating heart only transmits few pulsations to the wrist. The condition is not a disease in itself; it is merely a sign which may point either to grave conditions, or to what is practically physiological. The only point of importance is the means of diagnosis between the two groups.

A. PHYSIOLOGICAL.—(1) This variety may be congenital, present in several members of a family, and consistent with vigorous life; (2) it may develop in many old people; (3) it may be present in all states of hunger; (4) it may follow vomiting, an important sequence, as it may give rise to a groundless suspicion of cerebral disease; (5) it is often present during the puerperium; and (6) it may occur as a result of certain drugs, especially digitalis and the salicylic compounds.

B. PATHOLOGICAL.—(a) *Temporary.*—This form is very commonly met with in convalescence from acute diseases, especially pneumonia and influenza, and less often after diphtheria, enteric fever, erysipelas, and rheumatism. It is usually a good sign; it lasts a few days and then gradually passes off. If it does not pass off, and the pulse remains below 40 for some months, the prognosis is bad. This is especially noticeable after influenza. It is of very serious import if it occurs at the height of a fever, e.g. diphtheria, a pulse below 40 pointing to a fatal termination. It may also occur in jaundice, uræmia, and lead-poisoning.

Paroxysmal bradycardia is comparable to paroxysmal tachycardia, but much less common. Very few well-described cases are on record. A patient apparently in good health gets sudden attacks of slow-beating heart, with palpitation, dyspnoea, nausea and vomiting, even convulsions, and returns to apparently normal health after the attack is over. The cases are rare, and their pathology obscure. The condition does not occupy the well-defined position of paroxysmal tachycardia.

(b) *Permanent.*—A continuous pulse-rate below 40 lasting some months after an acute fever, e.g. influenza, is ominous. This form may be associated with nervous diseases, especially cerebral abscess, epilepsy, and affections of cervical vertebrae involving the spinal cord; or may accompany certain cardiac conditions, such as aortic stenosis, occlusion of the coronary arteries, and mitral stenosis. Bradycardia and organic heart-disease may be associated with recurring attacks of convulsions. The prognosis in these cases is generally bad, but a small number do well for even many years.

Pathology of the conditions leading to bradycardia.—Either (1) there is a temporary or a permanent lowering of activity in the cardiac centre of the medulla oblongata, due to various causes, among which are direct poisoning, exhaustion, lessened blood-supply; or (2) the heart itself is affected in its action by changes in its muscle, or blocking of its coronary vessels.

The treatment is that of the underlying conditions.
GUSTAVE SCHORSTEIN.

BRADYLALIA (*βραδύς*, slow; *λαλιά*, speech).—An abnormal slowness of utterance.

BRAIDISM.—SYNON.: Hypnotism.—Braidism is the name which, after its inventor, James Braid, has been applied to a therapeutic method destined to utilise the undoubted powers of mind over body for the cure of various diseases. In essence it consists of a species of Mesmerism, the patient being reduced to a partial or complete trance-like condition, by being made to look fixedly for a few seconds at a bright object held by the operator at 'about eight to fifteen inches above the eyes, at such a distance above the forehead as may be necessary to produce the greatest possible strain upon the eyes and eyelids, and enable the patient to maintain a steady fixed stare at the object.' The patient must be made to understand that he is to keep his eyes steadily fixed on this object, and his mind riveted upon the image of it. After so short a time as ten or fifteen seconds some patients may be intensely affected; and if so, it will be found, on gently elevating the arms and legs, that the patient has a disposition to retain them in the situation in which they have been placed. 'If this is not the case,' Braid writes, 'in a soft tone of voice desire him to retain the limbs in the extended position, and thus the pulse will speedily become greatly accelerated, and his limbs in process of time will become quite rigid and involuntarily fixed.' By slightly prolonging this process a condition of profound 'nervous sleep' may be induced, in which operations may be performed as easily and in as painless a manner as if the patient had been under the influence of chloroform. All this has been abundantly proved by Esdaile and others, who performed numerous operations upon Hindoos, with absence of all pain, while they were in the hypnotic state. In his attempts to cure morbid conditions, however, Braid only rarely proceeded so far as to induce actual unconsciousness. While in a semicataleptic condition the patient's attention is strongly directed to the morbid part, and some very marvellous instances of relief are recorded by him, said to have been effected under the influence of this faculty only, without the aid of imagination, since some of the patients operated upon were quite incredulous as to any good being likely to result. The method has now fallen into disrepute. This has been due to two causes. First, because of the facility with which it may be practised by non-medical persons, and the difficulty often experienced, even by medical men, in rousing persons from the state thus induced. And, secondly, because, even when practised by medical men, disagreeable consequences are apt to follow with some patients: fits may be induced, or the patient's moral and emotional control may be for a long time greatly impaired. The labours of many French physicians have however done much of late years to render definite and precise our knowledge of the various phases of hypnotism, of the modes in which they are inter-related, as well as concerning the best means of inducing or terminating this or that particular phase. See MESMERISM.

H. CHARLTON BASTIAN.

BRAIN, Abscess of.—See BRAIN and MENINGES, Septic Diseases of.

BRAIN, Anæmia of.—DEFINITION.—A condition in which the blood contained within the brain, and especially within the capillaries of the brain, is deficient in quantity, or defective in nutritive quality, or both.

ÆTIOLOGY.—*General cerebral anæmia* may be due to the following causes:—(1) It may be a part of systemic anæmia—defect in quantity or quality of the whole blood, due to causes which are considered elsewhere. This is often seen in cases of hæmorrhage, of exhausting discharges, or of defective blood-formation, as in chlorosis and pernicious anæmia. (2) The supply of blood to the brain may be deficient, the quantity of blood in the body being normal. The cerebral anæmia is then part of a cephalic anæmia. In consequence of posture in relation to gravitation, the supply of blood to the head is that which is especially interfered with by any interference with the movement of the blood. At the same time the fact that the brain is contained in a closed cavity, and the unreadiness of the cerebrospinal fluid to undergo rapid change of distribution, preserve the blood in the head from the extremely rapid diminution to which it would probably otherwise be liable—possibly, indeed, to a degree incompatible with life. Cephalic anæmia may be due to cardiac weakness, or to causes acting through the nervous system on the heart, as in swooning. In general anæmia, the lessened cardiac power increases the cerebral deficiency. Whatever lessens the amount of blood discharged from the heart at each systole, such as aortic or mitral disease, may be a cause of cerebral anæmia. Pressure on the vessels conveying the blood to the head, as by an aortic aneurysm, has a similar effect. Unequal distribution of the systemic blood is another cause. The intestinal vessels, if dilated, are capable of containing a large part of the blood of the body, and the effect of their engorgement is often seen after paracentesis abdominis. One theory of shock ascribes its mechanism to vaso-motor dilatation of these vessels, and consequent anæmia of the rest of the system. Severe diarrhœa or dysentery is an occasional cause of symptoms of a very pronounced and prolonged character. (3) The capacity of the cerebral vessels may be diminished by pressure on the brain, exerted by effusions of fluid (hydrocephalus), of blood (in cerebral and meningeal hæmorrhage), or by growths within the skull. (4) General contraction of the arteries of the brain is a supposed cause, probably confined to some toxic states, such as that of Bright's disease in which such contraction can be seen in the retina.

Partial cerebral anæmia is due to local obstruction to the passage of the blood through an artery. To be permanently efficient such obstruction must be situated beyond the circle of Willis. Ligature of one carotid causes immediate symptoms of cerebral anæmia, loss of function in one hemisphere, but permanent symptoms are not frequent. Pressure on, or disease of, one carotid, for the same reason, rarely gives rise to symptoms. Obstruction in certain arteries of the brain may cause local anæmia, sudden or gradual, temporary or permanent, according to its cause. Such obstruction may be due to narrowing of the calibre of the vessel by atheromatous changes in its wall, or may be due to actual occlusion by embolism or thrombosis. The pressure-effects of an intruding substance within the skull (tumour or clot) act most intensely in one region of the brain, and may influence it only. Arterial

spasm has been thought to be an occasional cause of local anæmia, but on doubtful grounds. Extensively as it has been invoked as a mechanism to explain symptoms, its occurrence has not yet received any definite proof.

It is obvious that of these causes some act suddenly, others gradually, and the symptoms produced will differ accordingly.

ANATOMICAL CHARACTERS.—The principal anatomical effect of cerebral anæmia is pallor of the brain, observable chiefly in the paler tint of the cortical substance, and the diminished number of red spots in the white centre. The pallor may be partial or general. The membranes are usually pale, but in some cases of partial anæmia they are hyperæmic from dilatation of the vessels and stasis in them. Effusion of serum in the meshes of the pia mater and between the convolutions may be found in general anæmia.

SYMPTOMS.—The symptoms of this condition vary according as the anæmia is suddenly or slowly produced, and as it is general or partial.

(1) In *sudden general anæmia* of the brain the sufferer feels drowsy; the special senses are dulled; noises in the ears and vertigo are complained of; the pupils are at first contracted; sight may fail; muscular power is weakened; respiration is sighing; the skin is pale, cold, and moist; nausea is common; and headache is rare. If the anæmia is more intense, consciousness is lost; there is universal paralysis; and general convulsions may occur, epileptic in character, these being especially frequent in sudden extensive loss of blood. The pupils dilate, and the coma may deepen to death. The loss of sight may persist in cases which recover, but secondary retinal changes are then found.

(2) When general anæmia of the brain is *slowly* produced, the state of the cerebral functions is usually that of 'irritable weakness.' Their action is imperfect in degree, and excited with undue facility. There is mental dulness and drowsiness; sometimes, however, insomnia is troublesome. Delirium is common in severe cases, and is conspicuous in some forms of imperfect blood-nutrition, as in the so-called 'inanition delirium.' Headache, usually general, is a common symptom. Sensory hyperæsthesiæ, tinnitus, *muscæ volitantes*, and vertigo are frequent. Convulsions are rare, but muscular power is generally deficient. All these phenomena are more marked in the erect than in the recumbent posture, especially when the erect posture is suddenly assumed. It has been remarked that some anæmic persons can think well only when lying down. In young children, after exhausting discharges, as diarrhoea, symptoms referable to cerebral anæmia are common, namely, somnolence and pallor, with depressed fontanelle and contracted pupils. The somnolence may deepen to coma with insensitive conjunctiva, and the coma increase to death. Such symptoms have been called *hydrocephaloid*, from some resemblance to those of 'acute hydrocephalus' (acute meningitis).

(3) *Partial cerebral anæmia* causes, if complete, loss of function in the affected area; and if it be permanent, as in obstruction of a vessel beyond the circle of Willis, necrosis of the cerebral tissue results (*see* BRAIN, Softening of). If incomplete and sudden, there is a temporary arrest of function. Ligature of one carotid artery, for instance, causes transient weakness and numbness in the opposite half of the body. There may be at first an over-

action of grey matter, causing, in certain regions, unilateral convulsions. The return of the blood-supply, as when a plug shifts its position or is broken up, may not immediately be followed by restoration of function, which may be put in abeyance for some time by the effect of the sudden influence. The loss of memory is occasionally of a remarkable character, involving only the power of retaining new impressions. If slowly developed, as in atheroma of arteries, pain and vertigo are common, with recurring local symptoms, such as numbness, tingling, and weakness.

In all cases of long-continued cerebral anæmia, prolonged damage to the nutrition of the brain may result. In the child the development of the brain may be arrested; in the adult, loss of memory and of general mental power indicates the deterioration of structure. These may last for many months, but commonly pass away at last.

PATHOLOGY.—The symptoms are, as already stated, dependent mainly on the defective quantity and quality of the blood circulating in the brain. Some influence may probably be ascribed to the diminution in the blood-pressure to which the nerve-elements are ordinarily exposed (Burrows). Nothnagel has pointed out that the symptoms indicate an early affection of the respiratory centre in the medulla, and of the cortical grey matter. The convulsions in acute anæmia have been ascribed to irritation of the medulla or of the pons Varolii, but our present knowledge suggests that they are due to the altered function of the motor region of the cortex. This has been confirmed by the discovery of changes in the motor cells in such cases; the staining particles found within the cells blend into a uniform mass, and the nucleus loses its central position, and may be sometimes extended. These changes are widely spread and explain the interference with function. When they have occurred to only a moderate degree the normal condition may be apparently restored.

DIAGNOSIS.—The diagnosis is not difficult. It rests on the recognition, in a given case, of the cause of cerebral anæmia; and on the exclusion of graver maladies, as organic cerebral disease. With the latter, it should be remembered, anæmia of the brain, local or general, often co-exists. Some symptoms of hyperæmia of the brain closely resemble those of anæmia. A common pathological state of imperfect blood-renewal exists in both conditions.

PROGNOSIS.—The extent to which the cause of the anæmia is amenable to treatment, and is of transient character, must influence the prognosis. As a rule this is favourable when there is no organic disease of heart, vessels, or brain. In pernicious anæmia, the prognosis is, of course, unfavourable. Hydrocephaloid symptoms in infants, if met by prompt and suitable treatment, are often recovered from.

TREATMENT.—The treatment necessarily varies in the several forms of the affection, but it is in the main causal. The beneficial effect of the recumbent posture in affording immediate relief to the symptoms, and obviating permanent damage to the cerebral nutrition, must be always remembered. In acute anæmia from loss of blood, the head must be kept continuously low, stimulants freely administered, and as a penultimate resort bandages applied to the limbs from below upwards may increase the proportionate supply of blood to the brain. If

this fails transfusion must be had recourse to. In chronic anæmia sudden change of posture should be carefully avoided, and ferruginous tonics are needed. More important than any other element is physical rest, permitting more of the scanty amount of oxygen that can be conveyed by the blood to be used for the nutrition of the protoplasm of the tissues on which the vital functions depend. All use of the oxygen by muscles should be avoided. In spasm of the cerebral vessels, nitrite of amyl or nitroglycerin may be employed; and a course of the latter, in a small dose two or three times a day, lessens any liability to irregular contraction that may exist. In the cerebral anæmia of syncope, the recumbent posture, stimulants to the skin, cold water, faradisation, sinapisms, and ammonia to the nasal mucous membrane, assist the recovery of cardiac action and the return of consciousness. In all cases, carefully regulated food and stimulants are needed; beef-tea should be given in small quantities at frequent intervals. The group of symptoms called hydrocephaloid requires similar treatment.

BRAIN, Hæmorrhage into.—**SYNON.** : Cerebral Apoplexy; *Fr. Hémorrhagie cérébrale*; *Ger. Hirnblutung*; *Hirnschlag*.

DEFINITION.—Escape of blood, by rupture of a vessel, into the substance or cavities of the brain. Hæmorrhage into the meninges is separately described.

Cerebral hæmorrhage is commonly due to the rupture of an artery; very rarely hæmorrhage into the ventricles is due to the rupture of a vein. Occasionally, minute extravasations are caused by rupture of capillaries, and may cause, by their number, an infiltration of the cerebral tissue with blood. This is seen in cases of venous thrombosis. Hæmorrhage from arteries or veins may also be due to their laceration by injury.

ÆTIOLOGY.—Arterial hæmorrhage is usually due to the coincidence of weakening of the vascular wall and increased pressure within the vessel. The changes in the walls permit the formation of military aneurysms which give way. Larger aneurysms may also cause cerebral hæmorrhage (see **BRAIN, Vessels of**). The causes of these conditions may be regarded as the conditions *predisposing* to cerebral hæmorrhage. Hereditary influence is sometimes distinctly seen, as a tendency to vascular degeneration, or to conditions which, as renal disease, produce such degeneration. Similarity of vascular distribution may also be inherited, and may determine the locality of strain, and, therefore, first of degeneration and expansion and ultimately of rupture. Cerebral hæmorrhage is most frequent after fifty years of age, but occurs at any age, though rare during the first half of life. It becomes

less common in extreme old age. It is nearly twice as common in men as in women. It is said to be more frequent in temperate than in tropical climates, in winter than in summer, and at high than at low elevations. Certain acquired conditions act as predisposing causes. Chronic Bright's disease leads to early and extreme degeneration of vessels, as well as directly to hypertrophy of the heart and increased blood-pressure; hence it predisposes powerfully to cerebral hæmorrhage. In purpura and scurvy, cerebral hæmorrhage occasionally occurs, and also in pernicious anæmia and leuchæmia. In the latter it is a not uncommon cause of death. In these blood-states the mechanism is doubtless impaired nutrition of the walls of the smaller vessels, which permits them to be bulged and thinned by a blood-pressure that may even be below the normal. The state of vascular repletion known as 'plethora' was formerly thought to be a frequent cause of cerebral hæmorrhage. It probably does aid other causes, but rarely co-exists with the more efficient, and so takes a subordinate position. Chronic alcoholism and opium-eating are said to promote vascular degeneration.

Among other remote causes must be reckoned heart-disease and syphilis, both of which commonly act by causing an aneurysm larger than those that are the special mechanism of hæmorrhage. Nevertheless, such aneurysms often escape even the most careful search.

The *proximate* causes of cerebral hæmorrhage are the weakened state of the wall of the vessel, and commonly some increase of blood-pressure. The vessel-wall is weakened by degeneration, and is often imperfectly supported in an atrophied brain. The increase of pressure within the vessels may be permanent, as in peripheral obstruction, with or without hypertrophy of the heart; or temporary, as in excited action of the heart, or impeded circulation through the lungs during effort. These causes are considered more fully in the article on **BRAIN, Vessels of, Diseases of**.

Hæmorrhage from a vein is rare, except as the result of laceration by direct injury, or of ulceration invading the vein from without. Varicose veins in the pia mater or ventricles may sometimes rupture.

Considerable capillary hæmorrhage is usually due to the venous obstruction already mentioned. It may also result from cephalic congestion due to any cause, from capillary embolism, and from the blood-states which cause larger vessels to give way. In all these blood-states similar extravasations are often seen in the retina from the same immediate cause.

ANATOMICAL CHARACTERS.—In intra-cerebral hæmorrhage, the blood is extravasated into the substance or into the ventricles of the brain—into the ventricles usually by rupture of a previous extravasation within the cerebral substance. In the latter situation the blood occupies a cavity formed by laceration of the brain-tissue; rarely, when very minute and 'capillary,' by merely separating the fibres. In size an extravasation varies from that of a pea or even smaller, up to that of the fist. The blood is found clotted, and reddish-black in colour; fragments of brain-tissue are mingled with it. The cavity containing it is often very irregular in shape; its walls are uneven, present projecting shreds of lacerated brain-substance, and are blood-stained and softened—at first by imbibition of serum, and later by inflammation.

CEREBRAL ABSCESS.

Female, aged 20 years. Four days after confinement developed symptoms, diagnosed as 'puerperal melancholia.' Some weeks later was admitted to an asylum in a stuporose condition, and died in three days. Cause of abscess was a left pyo-nephrosis following blocking of upper end of ureter by a calculus. Reproductive organs normal. Figure shows the abscess-wall formed by the markedly stretched frontal convolutions. The cavity was ragged, and contained irregular trabeculae and thick, greenish pus. The rest of the brain and membranes were very oedematous, but otherwise normal.

CEREBRAL HÆMORRHAGE.

Figure shows a hæmorrhage into the right external capsule which resulted in left hemiplegia. Death occurred 30 hours after the onset of symptoms. The site of the rupture into the right lateral ventricle, on the outer side of the anterior horn, is visible, as is also the blood-clot in the anterior and posterior horns of both the lateral ventricles.

J. S. BOLTON.

Many small extravasations are often seen in the neighbourhood of a larger clot. Usually there is only one large extravasation; sometimes, however, there are two or three. The extravasated blood exerts pressure; the convolutions are flattened; the falx is bulged to the opposite side; and the rest of the hemisphere is anæmic. The effused blood may tear its way into the lateral ventricle; it then speedily distends both lateral ventricles and the third and fourth ventricles, and may escape by the openings at the lower extremity of the fourth ventricle, central and lateral, into the subarachnoid space. Or the blood may escape to the surface, infiltrate the pia mater, and tear its way into the subarachnoid cavity, often by a very small opening. It is rarely that the artery from which the blood has escaped can be detected. Occasionally the extravasation can be traced to the rupture of an aneurysm of some size. In other cases miliary aneurysms may be found on many vessels. The larger arteries commonly present atheromatous changes, but these are only associated as the result of some of the causes, and especially of age.

After a time the extravasated blood undergoes changes. The clot shrinks and gradually becomes, first chocolate-coloured, then brown, and ultimately a reddish-yellow; and it then contains chiefly fat-globules, pigment and other granules, and hæmatoidin-crystals. The rapidity with which it undergoes this change varies. It is said that the distinctive blood-colour has disappeared as early as the twentieth day. Meanwhile the walls of the cavity undergo changes. The inflammation, in rare cases excessive and purulent, is usually conservative, and leads to the formation of connective tissue. A firm wall is thus developed, the inner surface of which ultimately becomes smooth by the softening and removal of the loose fragments of brain-substance; by this means a cyst is formed. It is said that connective tissue may extend across its cavity, and that in rare cases, the fluid being absorbed, the cyst-walls may unite, and a cicatrix result. Such cicatrices are, however, much more frequently due to softening than to hæmorrhage.

Hæmorrhage may occur in any part of the brain, but is more frequent in some situations than in others. The most frequent seat is the corpus striatum and the region just outside it: nearly half the intra-cerebral hæmorrhages are in this situation. Other primary seats, in the order of frequency, are the centrum ovale, the cortex, the pons and peduncles, the cerebellum, the optic thalamus (often affected by an extension of the hæmorrhage from the corpus striatum), the posterior portion and the anterior portion of the hemisphere. The frequency of hæmorrhage in the cerebrum is twenty times greater than into the cerebellum. The frequent extravasation into and outside the corpus striatum is explained by the vascular supply. As the rupture is often near the edge of the lenticular nucleus, the blood tears up the white substance; and this makes the frequency of primary hæmorrhage into the centrum ovale difficult to ascertain.

Traumatic hæmorrhage occurs into and from a lacerated portion of brain, and is most frequently found on the surface, occupying mainly the middle of the convex portion of each convolution, and some other regions much exposed to injury, as the surface of the temporo-sphenoidal lobe, and the under surface of the frontal lobe. Ventricular hæmorrhage sometimes results from traumatic rupture of a small

vein on the surface of the corpus striatum (Prescott Hewett).

Soft tumours (especially gliomata) are sometimes the seat of hæmorrhage. The distinction from simple hæmorrhage (sometimes difficult) rests on their position being commonly one in which cerebral hæmorrhage is rare; and on some gelatinous-looking tumour-substance being found, into which hæmorrhage has not occurred, and which has characteristic microscopic features.

Other organs may be healthy, or present the changes which have been mentioned as predisposing causes; the lungs are usually secondarily congested, often intensely.

SYMPTOMS.—The occurrence of cerebral hæmorrhage is indicated by cerebral symptoms of two classes, the one general and more or less transient, the other local and more or less permanent. In addition to these there are sometimes premonitory symptoms; and commonly general symptoms, manifested by pulse, temperature, &c., which are secondary to the brain-lesion.

Premonitory symptoms, somewhat rare, are those of altered cerebral function due to associated atheroma, headache, vertiginous feelings, local weakness or numbness, slight mental changes, and slight affection of speech (*see* BRAIN, Vessels of, Diseases of; and BRAIN, Anæmia of). But the disease causing them is commonly distinct from that causing the hæmorrhage. The miliary aneurysms cause no symptoms, and hence it is only in the case of aneurysm of larger vessels that there are true premonitory symptoms. Hence they are less frequent than in cases of softening.

The *onset* of hæmorrhage is usually accompanied by apoplexy, i.e. loss of consciousness and of power of motion and of sensation, often with relaxation of the sphincters and loss of reflex action (*see* APOPLEXY, CEREBRAL). These symptoms are profound and lasting, according to the size of the hæmorrhage and its position; being especially marked in large and double effusions, in intra-ventricular hæmorrhage, and in hæmorrhage into the pons. In a case of moderate severity they last only a few hours, and gradually pass away. In severer cases they may deepen until death occurs from failure of respiratory power. Death is rarely very speedy, life being usually prolonged for some hours even in the most rapidly fatal cases. In rare instances of hæmorrhage into the medulla, and also in meningeal hæmorrhage, death has occurred in five minutes, probably in each case from the rapid interference with the respiratory centre.

The temperature is at first lowered one or two degrees; the pulse becomes less frequent; and the respiration slow. The Cheyne-Stokes respiratory rhythm often precedes death. After a few hours the temperature rises to the normal and in mild cases stops there, but in graver cases it rises above the normal two or three degrees. In some very grave cases the initial fall or subsequent rise may be extreme and go on until death occurs, sometimes reaching 90° in the one case, and 107° or 108° in the other (Bourneville). The urine is at first abundant, of low specific gravity, and acid in reaction.

In slight cases of cerebral hæmorrhage there may be no loss of consciousness. Vomiting in such cases is not infrequent. In other rare cases of large hæmorrhage, especially between the external capsule of the corpus striatum and the island of Reil (Broadbent), the loss of consciousness comes on

gradually, after other symptoms, as of shock, for example, have lasted for an hour or two. These cases have been termed *in Gravescent*.

Local symptoms, chiefly unilateral, often permanent, and always of longer duration than the loss of consciousness, are present in all cases of circumscribed cerebral hæmorrhage, except in the instances in which, by its central position in the pons and medulla, it causes directly bilateral effects only, which are added to and intensify the general symptoms caused indirectly. In a unilateral cerebral lesion, the direct symptoms are unilateral loss of power of voluntary movement and often of sensation, accompanied sometimes by convulsion or rigidity. These local symptoms may commence a few minutes or longer before the loss of consciousness. They co-exist with the apoplectic condition, and may often be recognised, even during coma, by the flaccidity of the paralysed limbs, which fall more helplessly than those of the opposite side; by inequality of the mouth and of the pupils; by conjugate deviation of the head and eyes towards the side of the brain injured; by convulsive movements; and, as the apoplexy clears, by the detection of unilateral defect of sensibility. The coma passing away, these signs become more distinct, and all the symptoms of hemiplegia remain, varying in intensity and extent according to the position of the lesion. The apoplectic state may recur after its disappearance—a grave symptom, usually indicating that a fresh hæmorrhage has occurred in the same or the other side of the brain, or more frequently that the blood has escaped into the ventricles. In the former case the unilateral symptoms, conjugate deviation of the head and eyes, &c., are increased on the same, or transferred to the opposite side; in the latter the unilateral symptoms disappear, and general powerlessness and deep coma supervene, with stertor, relaxation of the sphincters, lowered temperature, and impeded respiration. Death always ensues.

Convulsion may be a conspicuous symptom at the onset or subsequently. It is usually unilateral in its course or commencement, beginning on the side paralysed, rarely affecting only the non-paralysed side. In cases in which the blood escapes slowly, convulsions may occur on one side, and in the course of an hour or two may cease, the side at the same time becoming powerless. This is due to the motor structures, commonly those of the cortex, being at first irritated by the hæmorrhage, and afterwards interrupted or compressed so as to be incapable of function. Where convulsion is not met with, muscular twitching or rigidity may occur. General or widely spread rigidity or twitching points to a bilateral lesion; if with coma, to ventricular hæmorrhage.

After a day or two symptoms of irritation about the cerebral lesion come on, such as headache, delirium, and rigidity in the paralysed limbs. During this period the temperature rises above the normal, and the pulse becomes quick. On their subsidence these symptoms, if the lesion is slight, may be scarcely recognisable, and a stationary period ensues, at the end of which recovery of power over the paralysed limbs begins. In slight cases power may be recovered very speedily. Its return depends upon the structural recovery of slightly damaged tissue, and on other parts taking on an increased function in compensation for that which is destroyed. The electric irritability of the muscles exhibits little change. Sometimes, how-

ever, when there is great irritation at the lesion propagated downwards to the cord, a marked initial increase in the irritability may precede a considerable depression, coincident with rapid wasting. Recovery of power is rarely complete except in those cases in which the area of damage is very small; and when the damage is large and affects an important motor region, there may be no recovery, loss of power persisting, commonly with more or less 'late rigidity' in the paralysed limbs. Slight permanent mental change often remains, and as the motor power is recovered, ataxic and other disorders of movement may supervene in the limbs which were paralysed, although much less commonly than after softening.

DIAGNOSIS.—The diagnosis of cerebral hæmorrhage rests on the symptoms of a localised cerebral lesion occurring suddenly. The conditions from which it has most commonly to be distinguished are—congestion of the brain; softening of the brain, embolic and thrombotic; and sometimes tumour. For the distinction from it of other causes of apoplectic loss of consciousness, uræmia, post-epileptic coma, &c., see APOPLEXY, CEREBRAL.

From *congestion* the chief distinction of the cerebral hæmorrhage lies in the transient nature of the loss of consciousness and in the slightness and general character of the symptoms which characterise the former. Congestion generally, hæmorrhage only sometimes, comes on during effort; and the absence of history of effort is in favour of the latter. Similarly, the premonitory symptoms which are usually present in congestion are generally absent in hæmorrhage. The loss of motor power, and symptoms of cerebral shock, are much greater in hæmorrhage than in congestion. It must be remembered that the two states may co-exist.

From *softening* consequent on *embolism* cerebral hæmorrhage has also to be distinguished. The subjects of the latter are usually of an earlier age than those of hæmorrhage; their vessels are healthy, but they have organic heart-disease, which is often grave. There may be evidence of embolism elsewhere, in spleen, kidney, or retina. Loss of consciousness is often absent in embolism, and the paralysis may come on suddenly or deliberately, and is sometimes brief in duration but sometimes enduring. Deep apoplectic coma should always lead to a suspicion that hæmorrhage is the lesion, and this especially in cases of young persons with heart-disease. It is important not to let the presence of heart-disease exclude the idea of hæmorrhage, because it is in such cases that the most severe forms of hæmorrhage are met with, in consequence of aneurysm, due to embolism, which has ruptured.

From *softening* due to *thrombosis* the distinction is often difficult. Age is no longer significant, since both occur in later life, but thrombosis is more common in extreme age. The presence of chronic Bright's disease is slightly in favour of hæmorrhage; but atheroma, the cause of softening in later life, is also induced by it. In middle life advanced kidney-disease makes hæmorrhage far more probable. The most important diagnostic indications, however, are those drawn from the state of the heart and circulation, whether these are such as to conduce to the rupture of an artery or to allow clot to form in it. On the one hand we have a full or tense pulse and hypertrophied strongly acting heart; on the other a feeble pulse and weak often irregular heart. These indications

are of great weight. Excitement at the time of the onset suggests hæmorrhage; depression, physical or mental, suggests softening. The occurrence of previous slight hemiplegic or other cerebral attacks points to softening. In the attack, loss of consciousness is much more considerable, in proportion to the subsequent paralysis, in hæmorrhage than in softening. But the distinction on this ground is often very difficult, since loss of consciousness may be absent in slight hæmorrhage, and considerable in an extensive softening. A deliberate onset is in favour of softening; and so are much mental change, and early rigidity. A definite fall of temperature is generally caused by rupture of a vessel, and so also is a rise within twelve hours. Paralysis of sudden onset, in cases of *tumour*, may be ascribed to hæmorrhage into the growth, to which it is generally, but not always, due. Usually, enquiry elicits a history of gradual, long-continued symptoms; headache and intense optic neuritis are strongly suggestive of a tumour into which a hæmorrhage may have occurred, but moderate optic neuritis may be the effect of Bright's disease and is often associated with headache.

Hæmorrhage into the substance of the brain is distinguished from *meningeal hæmorrhage* by the pain and mental excitement being less conspicuous, convulsion rarer, and by the presence of symptoms of a local lesion. *Hæmorrhage into the ventricles* resembles meningeal hæmorrhage in the generality of its symptoms, but these usually succeed the symptoms of a circumscribed lesion.

PROGNOSIS.—During the early stages of the attack the prognosis in hæmorrhage into the brain must be guided by the intensity of the symptoms, and by the place of the lesion, as far as that can be ascertained. Death is probable if the coma is profound, or has not begun to lessen at the end of twenty-four hours, and if the early depression, or the subsequent rise, of temperature and pulse-rate is great. Most cases are hopeless in which there is marked interference with respiration—even hicough is a cause of anxiety. When the symptoms indicate ventricular hæmorrhage, or hæmorrhage into the pons, there is little chance of survival. In meningeal hæmorrhage with coma the prognosis is exceedingly grave. After some consciousness has been recovered, most of the danger of immediate death is over, the freedom from much secondary pyrexia, from lung-congestion, and from early bed-sores, are favourable indications. The chance of recovery from the paralysis is estimated by evidence of position of the lesion, and especially by any indications of improvement. In most cases the power of standing and walking, at least a little, returns, because each leg can be innervated to some extent by the hemisphere of the same side. Recovery of the hand can only be foretold by the observed degree of movement regained, and its rapidity. Early rigidity is unfavourable. The danger of recurrence is in proportion to the extent of vascular disease, and the existence of irremovable causes of increased arterial tension. Hence the prognosis is rendered unfavourable by advanced age, or chronic renal disease, and by the evidence of general premature decay.

TREATMENT.—*During the attack.*—Rest is the most important. The patient should remain, as far as possible, where he is seized; stillness must be secured, and all effort avoided. The posture

should be recumbent, with the head raised, but without flexion of the neck. Any cause of passive cerebral congestion, such as a tight collar, must be removed. Venesection was formerly almost always employed in such cases—certainly too universally, but is now discarded—perhaps too absolutely. Loss of blood lessens the force of the heart and vascular tension; it thus hastens the cessation of hæmorrhage. It may be used with probable advantage if the pulse is full, bounding, and incompressible, the heart acting strongly, and there is reason to believe that the intracranial hæmorrhage is increasing. A small quantity of blood (e.g. eight ounces) should be withdrawn rapidly. In ventricular hæmorrhage, venesection is probably powerless for good. When the indications are not perfectly clear, it is not wise to employ a measure now out of fashion.

The object to be aimed at by other measures must be to lower the arterial pressure by diverting the blood as far as possible from the brain. If the limbs are cold, warmth may be applied to them, aided by sinapisms. Purgatives, as croton oil or calomel, will divert the blood to the capacious intestinal vessels. Drugs which would cause contraction of the vessels are to be avoided, since, their influence being on the smallest vessels and universal, their tendency is to increase arterial tension and hæmorrhage. To this, however, digitalis is an exception, since its action seems to be chiefly on arteries not smaller than those that burst. Diuretics are useful for the same object; nitrous ether and juniper may be combined with digitalis. An attempt may be made to promote contraction of encephalic vessels by cold to the head or sinapisms to the neck, according as the head is hotter or colder than normal. The heart should be allowed to fall a little below the normal in force, but conspicuous failure of power should be avoided. Convulsion is effectually checked by ice to the head; bromide may be given if there is a tendency to the recurrence of convulsions.

After the attack.—During the stage of irritation, rest must be maintained, and the patient preserved from all sources of excitement. The bowels should be kept gently open by laxatives or by injections. Stimulants must be avoided, and the diet should be light. Pain or delirium may be relieved by cold to the head, a blister to the neck, or by Indian hemp, bromide of potassium, or a small dose of hydrobromate of hyosine.

During reparation the diet must be nutritious, but carefully regulated; and constipation of the bowels avoided. Upward massage of the limbs, and their gentle passive exercise, are wise; and after all symptoms of irritation have passed, say in two months, gentle faradisation may improve muscular nutrition, and accelerate any distinct return of power. Nervine tonics probably aid a little the recovery of slightly damaged structures: quinine and strychnine or very small doses of phosphorus if there is no kidney-disease. But their influence is small. As a rule the spontaneous tendency to such recovery as the destruction of brain-tissue permits, obscures the influence of therapeutical measures. But these may wisely be adopted in the hope that they have some influence in augmenting the gradual improvement. Change of scene, and cheerful mental surroundings are useful adjuncts, especially in the later stages of recovery.

W. R. GOWERS.

BRAIN, Hyperæmia of.—**SYNON.** : Congestion of the Brain.

DEFINITION.—Increase in the quantity of blood within the capillaries of the brain, other than that which is merely the early stage of inflammation.

Since neither the arteries nor the veins of the brain-substance can be over-distended with blood without capillary hyperemia, and since it is to capillary hyperæmia that the functional disturbance of the brain is related, this may be justly taken as the essential pathological element in cerebral congestion. The congestion may be *active*, when the capillaries contain, in consequence of arterial distension or dilatation, an increased amount of oxygenated blood passing rapidly through them; or it may be *passive*, when, from venous obstruction, the increased blood in the capillaries is slowly moving, and is becoming, or is in great part already, venous.

'Congestion of the brain' is often alleged because no other explanation of symptoms occurs to the mind of the practitioner, although there may be no real evidence of such a state. Like 'congestion of the liver,' it is often adopted merely because it is a convenient refuge for a destitute diagnosis, and pleases the patient as an explanation which both satisfies and gratifies him. Indeed, it is a malady of which both symptomatology and pathology are open to much question. Its existence should never be assumed on purely negative evidence. Its assertion is often so groundless as to be most discreditably to the profession. Some descriptions of it have been written entirely from cases of the cephalic sensations that attend hypochondriasis.

ÆTIOLOGY.—(A) *Active* congestion of the brain may be general or partial. Of the *general* form the *remote* causes are as follows:—Men are said to be more liable to it than women. Age increases its frequency, chiefly from the greater frequency of its causes; yet children, from the sensitiveness of their vaso-motor system, occasionally seem to suffer from an active form. The 'plethoric' condition, with its tendency to general overfilling of the vessels, is a predisponent. The *immediate* causes of excessive flow through the arteries of the brain may be thus stated: (1) Increase in the blood-pressure—either general, from excessive action of the heart (as in extreme hypertrophy or functional overaction); or partial, from an obstruction elsewhere, throwing an undue proportion of the pressure upon the cerebral vessels. This is seen in contraction of the aorta beyond the origin of the vessels to the head, and in sudden contraction of a large number of the systemic arterioles, as those of the surface, in exposure to cold and in ague. It may result from cardiac excitement, whether due to mental or physical causes. (2) Active arterial dilatation of vaso-motor origin may be excited by prolonged mental work, severe emotion, insolation, digestive disturbances, or from the presence in the blood of various poisons, such as alcohol, and amyl-nitrite or nitroglycerin. In these cases the vaso-motor disturbance may precede and cause, or may succeed and result from, the overaction of the brain-tissue, which is intensified by it. It results from the cardiac excitement of exophthalmic goitre. It seems to occur in the second stage of many attacks of megrim. In alcoholic poisoning the cerebral congestion may be in part, as Niemeyer suggested, secondary to the disturbance of brain-tissue, although the simultaneous flushing of the face makes this doubtful. In pyrexia the headache and delirium have been thought to be due to conges-

tion, but they more likely result from the blood-state. (3) Lessened atmospheric pressure may cause congestion of the brain, as in the 'Zenith' balloon-catastrophe; and it probably occurs when divers pass from the increased to normal pressure. (4) Gravitation in the recumbent posture may alone cause cerebral hyperæmia, or may powerfully aid other causes in producing it.

Partial active congestion of brain-tissue occurs chiefly from disease of the arteries, which perverts the local distribution of the blood-pressure; in organic brain-diseases, as tumour, hæmorrhage, &c.; after blows on the head; and probably also from local overaction of special centres. In many of these cases it is really a slight and transient condition which is indistinguishable from that of local inflammation.

(B) *Passive* congestion of the brain, when *general*, is the result of impeded return of blood from the head. It is intense in death from all forms of suffocation or by hanging. It may be due to pressure on the veins in the neck, as by tumours; pressure on the innominate veins by tumours or aneurysm; or obstruction to the circulation from violent respiratory efforts, as exertion, cough, or blowing wind-instruments. It may be caused by impediments within the circulation, such as tricuspid insufficiency and its causes in the lungs, or even by disease on the left side of the heart. The recumbent posture assists all these influences.

Partial passive congestion may occur from pressure on a cerebral vein, from local venous thrombosis, or from pressure by a growth on one of the cerebral sinuses.

ANATOMICAL APPEARANCES.—The capillaries are not visible to the naked eye even when over-distended, but with the microscope they are seen to be dilated, often to twice their normal calibre. Their distension is indicated by a deeper and reddish tint of the grey substance; and the fulness of the small arteries and veins shows itself in an increase, often very great, in the number and size of the red points visible on section of the white matter. In active congestion the arteries may be distinctly larger than normal; the minute vessels of the meninges are also distended. Indeed in all forms of general congestion, the state of the vessels is generally more distinct in the pia mater than in the substance of the brain. In all, however, it is chiefly the active congestion that would pass on to inflammation, or is really its first stage, that leaves distinct traces. In passive congestion the veins and sinuses are gorged with blood. It must be remembered, however, that such engorgement of the veins occurs in all cases of death from interference with the passage of the blood through the thorax. The state of the cerebral veins must therefore be carefully compared with that of the veins of other organs. Active congestion may sometimes leave no visible traces. After a time blood-pigment collects outside the vessels (Bastian), and serous effusion into the membranes and ventricles may be found. Later on the vessels may be permanently distended; degenerative changes, consequent perhaps on the effusion of serum, may lead to the production of wide spaces around them; and the whole brain may have undergone distinct wasting. It must, however, be pointed out that the absence or paucity of *post-mortem* evidence of active congestion is equally true of the skin, and does not establish its absence during life.

SYMPTOMS.—It is probable that many symptoms

have been erroneously ascribed to cerebral congestion; some because hyperæmia, due to the mode of death, was found *post mortem*; others because an assumed congestion was the readiest explanation.

The symptoms commonly referred to cerebral congestion may be grouped in two classes—those of excitement, and those of depression. Either of these may exist alone; those of excitement may precede those of depression; or they may partially co-exist. They may be slight or severe; acute or chronic. In all cases they are increased by the recumbent posture or depressing the head, by expiration, cough, and effort; and they are usually aggravated by constipation, and by indulgence in alcohol.

1. *General*.—Among the symptoms of excitement may be mentioned mental irritability; headache, slight or violent, with feelings of fullness or throbbing in the head, and vertiginous or other sensations; derangement of the special senses, such as flashes of light and noises in the ears; contraction of the pupils; sleeplessness; restlessness, startings, twitchings or slight actual convulsions; and mental excitement. The pulse is quick. There may be vomiting. The face may participate in congestions of circulatory origin. In other forms of supposed congestion, as in those which result from excessive brain-work, the face may be pale, but the nature of these cases is doubtful.

Among the symptoms of depressed brain-function are dulness of the special senses; motor weakness; mental indifference and slowness; somnolence, especially after meals; dilatation of the pupils; and infrequency of the heart's action. Consciousness may be lost suddenly, and the loss, it is commonly believed, may deepen into coma, but this is seldom absolute. As a rule there is no fever, but in children the temperature may be raised.

In the *chronic* forms of cerebral congestion, these symptoms, variously grouped and moderate in degree, continue for days, weeks, or months. Their course is marked by great variability.

In the more *acute* forms of cerebral congestion, the symptoms of muscular spasm, of mental disturbance, or of loss of consciousness, may be so predominant as to give a special character to the attack:—

a. In the *convulsive* form pain or uneasiness in the head commonly precedes the muscular spasm. The latter is usually deliberate in onset. It is said sometimes to be unilateral at first, and afterwards general, but more frequently it is general throughout. Tonic may precede clonic spasm, and the attack resemble an epileptic fit, or clonic spasm only may be present, or slight general tonic spasm. The writer has witnessed in an adult a general attack of clonic convulsions as a result of a violent attack of cough, causing extreme cyanosis.

b. The *delirious* form is seen under two aspects—(1) in old age, after emotional excitement; in this the wandering is slight, and often related distinctly to the recumbent posture, or to a low position of the head; (2) a much more violent delirium, which may be due to cerebral congestion (but is less distinct in nature), is seen sometimes after mental work or emotional excitement, or after alcoholic poisoning. It often resembles and may end in mania, but there is no pyrexia. Occasionally death results.

c. The *apoplectic* form is marked by sudden loss of consciousness, occurring commonly during effort in

plethoric persons. The unconsciousness usually lasts only a few minutes, and slight general weakness may remain for a day or two. In rare cases the loss of consciousness deepens into coma, with stertorous breathing and relaxed sphincters, and death may occur from the extension of the cerebral depression to the respiratory centres without any distinct lesion of the brain. It is doubtful if such cases should be regarded as examples of mere congestion.

d. *Vertiginous* sensations sometimes give a character to an attack. In children congestion of the brain is said to be a rare but occasional cause of convulsion or delirium. Headache and contracted pupils make up a group of symptoms resembling meningitis, but fever is rarely present, and if it exists it is slight, and the symptoms usually come on suddenly and pass away in a day or two. Death, however, sometimes occurs soon after the onset, especially in the convulsive form. The nature of such attacks is open to doubt. But children sometimes pass rapidly into a state of headache, intolerance of light, and considerable fever, often with vomiting, and recover completely after twelve or twenty-four hours. Such attacks may occur periodically and are ascribed to 'congestion of the brain.' The subjects, however, usually become liable, subsequently, to characteristic *mègrim*.

2. *Partial*.—Partial hyperæmia leads to localised symptoms of excitement or depression of function. Limited convulsion or paralysis may result. Headache may be intense and local. If nothing more than congestion is present the symptoms usually soon pass off, but such cases are extremely rare, to say the least.

PATHOLOGY.—The possibility of the variations in the quantity of blood within the brain has been denied on the ground that the cerebro-spinal circulation is carried on within a closed cavity. But the statement is untrue in the sense that is relevant to the problem at issue, since the communication of the venous sinuses of the skull, and especially of the venous plexuses within the spinal canal, with external vessels, is free, and affords a ready mechanism by which the amount of blood, even in the distant cerebral vessels, may be varied by the displacement of the cerebro-spinal fluid. This, it will also be remembered, can pass into the perivascular spaces, and can readily yield to increased intravascular pressure, and thus make room for an increase in the quantity of blood within the arteries or veins.

An excessive supply of arterial blood is, in all organs, attended with functional activity, and it is easy to understand that active congestion should result in symptoms of excitement (mental activity is often conspicuous in the subjects of aortic regurgitation, in which arterial pulsation is so vigorous). Subsequent depression of function has been accounted for by inferring compression of brain-tissue by effused serum. The reaction of exhaustion may contribute. In passive congestion the nerve-tissue is imperfectly supplied with oxygenated blood, and its functions are impaired by the presence of effete product. Hence the predominance of symptoms of depression over those of irritation.

DIAGNOSIS.—The diagnosis rests on the discovery of circulatory and other causes of cerebral congestion; on the circumstances of posture, effort, &c., under which the symptoms came on; on the

existence of concomitant congestion in other adjacent parts ; on the general character of the cerebral symptoms ; on their speedy disappearance ; and on the absence, in the adult at any rate, of material elevation of temperature. The diagnosis of the special forms of cerebral congestion from the diseases which they most resemble is considered under the head of those diseases. It may, however, be mentioned that persistent focal symptoms exclude mere congestion. On the other hand, the condition is most improbable in cases in which the various cephalic sensations of pressure, fulness, heat, &c., seem to the hypochondriacal sufferer to be certainly due to this condition. It is in these cases that it is within the power of the doctor to do great harm by encouraging the erroneous opinion.

PROGNOSIS.—The prognosis is generally immediately favourable ; but it must always be determined by the gravity of the symptoms. In a severe attack of any form of supposed congestion death may occur. The apoplectic form is most dangerous, the convulsive least so. Degenerated vessels increase the immediate risk to life. After many attacks, permanent nutritional changes in the brain often supervene.

TREATMENT.—The most important elements in the treatment of definite cerebral congestion are posture, removal of blood, purgation, cold to the head, and warm and stimulating applications to the surface. Whatever be the cause of active congestion, it is important to raise the patient's head, so that gravitation may impede the flow and aid the return of the blood. By this means alone, insomnia from this condition may often be prevented. The removal of blood is useful in extreme forms of congestion, either active or passive, especially in those forms of active congestion in which the face participates. Venesection or leeching behind the ears may be employed, according to the severity of the attack. The relief which, in such cases, follows epistaxis illustrates the benefit thus afforded. We cannot indeed induce such direct relief, but a leech may be applied behind the ear, where there are communications between the circulation inside and outside the cranium. This is not advisable in those cases in which, from over-action of brain tissue, we may assume encephalic congestion while the surface remains pale. In most forms of congestion, especially in plethoric states, purgation is useful. It removes from the blood some of its serum, and it affords immediate relief to the cerebral circulation, by causing an afflux of blood to the capacious intestinal vessels. Diuresis is also useful. Cold to the head is of most value in reflex or secondary dilatation of the cerebral vessels, as after mental work, insolation, fatigue, and in some toxæmic states. In the same class of cases, stimulation of the peripheral nerves by sinapisms, blisters, &c., applied to the neck, and even to the soles of the feet and calves, will not only draw blood to the surface, but also, by reflex influence, assist in obtaining arterial contraction. Hot applications to the limbs act in a similar manner, causing local afflux of blood and thus lessening the tendency to encephalic engorgement. Recourse may also be had to mechanical appliances for increasing the quantity of blood in the limbs. This element in treatment is most useful in active congestion. Alcohol and opium should be avoided in all forms of active congestion, but in passive congestion they may be of service. Bromide of

potassium is useful in those cases in which the congestion is produced by vaso-motor disturbance. In passive congestion from heart-disease the treatment is that of the cardiac condition, digitalis, strophanthus, and diuretics being of especial service. All persons liable to congestion of the brain should live regularly, avoid hot rooms, and attend carefully to the stomach and bowels, keeping the latter regular by an adequate daily aperient.

W. R. GOWERS.

BRAIN, Hypertrophy of.—This term is applied to an overgrowth of the interstitial tissue of the brain, the nerve-cells and fibres being often actually diminished both in size and number. The condition must be distinguished from some forms of œdema, in which the whole brain may be considerably larger than normal, and also from a normal brain of unusual size. In this so-called hypertrophy, the brain may or may not be larger than usual, but its density is considerably increased ; beyond this the naked-eye examination often shows nothing unusual. In other cases many of the convolutions are slightly raised, are quite smooth and extremely hard ; while the pia-arachnoid is detached from them with great ease. On cutting through one of these, considerable resistance is felt, the section is pale, smooth, and somewhat mottled, and the cortical striæ are obscured. In some instances small dense globular excrescences may project from the walls of the lateral ventricles. The disease is most common on the superficial parts of the brain, but any such part may be affected.

On microscopical examination of one of these portions there is seen to be a great increase in the number of neuroglia-cells, their processes are very numerous, much thickened, and form a dense network ; the nerve-cells may be fewer in number and slightly atrophied, their arrangement being most irregular, so that it is almost impossible to make out the ordinary cortical layers. The perivascular connective tissue may be also slightly increased, but as a rule the vessels themselves are unchanged. In addition to these somewhat localised aggregations of neuroglia, there is a general increase of glia throughout the organ, and this with the absence of vascular change or of secondary degeneration suffices to distinguish the condition from disseminated sclerosis and secondary change following vascular lesions.

ÆTIOLOGY AND SYMPTOMS.—The cause of this condition lies in a developmental error ; there is a tendency to undue growth of neuroglia similar to that occurring in some forms of syringomyelia, and this may be associated with a defective development of the nervous elements. The subjects of the disease frequently come of a neurotic or insane stock ; they are usually either imbeciles or epileptics, often both. Beyond this the condition does not appear to give rise to any sensory or motor disturbances, and there are therefore no certain means of recognising it during life. A. F. TREGOLD.

BRAIN, Injuries to the.—These will be considered under the headings of *concussion* and *compression*.

I. Concussion.—As the result of a violent blow or fall upon the head the brain may be severely shaken within the cranium, the elasticity of the latter also allowing of considerable squeezing or temporary compression being applied at the moment of the injury. The mere shaking of the

cerebral mass accounts for the symptoms of 'concussion' in slight cases, but it is certain that in the more severe examples of concussion there are definite organic lesions present. Of these the chief are hæmorrhages from the thin-walled blood-vessels on the surface of the brain or into the cortex. Should it happen that veins of fair size in the pia or dura mater have been torn, the resulting hæmorrhages may be so extensive as to cause actual symptoms of compression, but more commonly the extravasations are scattered widely, each being attended with localised tearing or bruising of the delicate tissues of the brain at that spot.

In the case of injuries to the head from falls or blows without perforation, certain definite parts are prone to suffer from contusion and laceration. Usually some slight evidence of injury is found immediately beneath the part of the skull upon which the blow was received, but by far the chief bruising will be at the opposite point; thus if the occiput be struck, the anterior lobes will be contused, and if one parietal eminence, the opposite temporo-sphenoidal lobe. This law, however, is greatly modified by the differing conditions under which different parts of the brain-mass are placed. In the posterior half of the skull the brain-mass is bulky, and between its hinder lobes and the cerebellum is a strong flexible membrane, well calculated to break vibrations gradually, and thus to prevent contusion. Nor are there in these regions any strongly marked bony ridges against which the brain might be forced. These conditions are reversed as regards the frontal and temporo-sphenoidal lobes, and the consequence is that while severe contusions are often seen in the latter, they are much more rare in the cerebellum and posterior two-thirds of the hemispheres. In cases of compound fracture, with tearing of the dura mater and deep depression of bone, the brain-substance may, of course, be injured at any part, but even in respect to this kind of violence the hinder regions of the skull are specially protected. Occasionally the contusion of part of the brain with its attendant hæmorrhage gives rise to localising symptoms. Thus injury to the left inferior frontal convolution may produce aphasia, to one or other part of the ascending frontal and parietal convolutions weakness of the opposite arm or leg or of some group of muscles in either limb (see Fig. 1, in BRAIN, Tumours of). Such paralytic symptoms following concussion are as a rule wholly recovered from after the lapse of a few days or weeks. This is, unfortunately, not always the case if one or other of the cranial nerves have been torn across or otherwise damaged at the time of the injury to the head. The olfactory lobes, the optic nerves, and occasionally the third, fourth, or sixth nerves have been known to be completely and permanently paralysed as the result of a severe fall on the head, and this is most likely to occur if a fracture of the cranial base has passed through the foramina at which the nerves involved emerge. With a fracture of the middle fossa either the facial nerve in the aquæductus Fallopii or the auditory nerve is often damaged. These injuries to cranial nerves are so important from the point of view of prognosis (since they are likely to prove permanent in their results, while the recovery from the accompanying concussion of the brain is in most cases complete) that they should be carefully sought for in every case. Their occurrence is to be suspected whenever

the parts supplied by a cranial nerve are completely paralysed without accompanying symptoms indicative of severe lesion of the brain-mass. Here it should be noted that even small traumatic hæmorrhages into certain parts of the brain have an importance quite out of proportion to their size, owing to their special site. Thus in some cases of concussion which have proved fatal, punctiform hæmorrhages have been discovered in the pons Varolii and floor of the fourth ventricle, where the cardiac and respiratory centres are placed. In such examples of fatal concussion the whole surface of the brain is found to be intensely congested at the time of the *post-mortem* examination. We may safely assume that in all severe cases of concussion which do not prove fatal, i.e. the great majority, there is immediately after the injury a period of shock and depression of the heart's action in which the brain is comparatively bloodless, and its functions therefore suspended, but that this stage is succeeded by a reaction in which all the cerebral arteries dilate and the whole brain becomes engorged with blood, especially the parts situated near the surface (see BRAIN, Congestion of). This high degree of congestion no doubt explains the severe headache so constantly met with, and may also account for the occasional occurrence of general epileptiform convulsions. The latter are more frequently met with in children than in adults, and may be so severe and so frequent as to threaten a fatal issue. It is important to remember that the administration of a general anæsthetic (ether or chloroform) will probably put an end to such dangerous convulsions.

SYMPTOMS.—In slight cases there is no real unconsciousness, merely a temporary giddiness and loss of brain-power, succeeded by headache with perhaps some strange or inconsequent action. In the gravest cases there may be found prolonged insensibility, and then the periods of reaction and of gradual recovery are of equally long duration. The symptoms may be conveniently grouped into four stages. The first stage is that of *collapse*, in which there is more or less complete loss of consciousness, pallor of the skin, and coldness of the extremities, due to feebleness of the heart's action, the respiration showing a similar depression and being shallow and feeble. In fact, the condition and appearance of a man badly concussed may closely simulate death, and the mistake has frequently been made on the field of battle and elsewhere. The state of the pupils is neither constant nor of any practical importance, so long as fixed mydriasis be not present, in which case compression of, or very severe damage to, the brain is to be suspected. It is of great importance, in this stage, to establish the absence of all forms of paralysis. If any asymmetrical symptoms are present, the case is more than concussion. The second stage is that of *Reaction*. After the collapse has lasted some little time (half an hour to two, three, or more hours), it begins to pass off. The patient moans, manifests discomfort, turns on his side, and draws his knees up. Very often at this period sickness occurs, and it is almost invariable if the patient's stomach was full at the time of the accident. Consciousness is now usually restored, and, by rousing, the patient may be induced to speak and to tell his name. Gradually during a period of some hours the case passes into the third stage of *drowsiness*. The pulse is now relaxed and full, the skin warm or even hot, the

face somewhat flushed, and the pupils contracted. The patient can only be awakened with difficulty. It is, however, always possible to awaken him, and he usually rouses himself to the calls of nature. His answers to questions are often confused or irrelevant, and there may be extreme irritability on being roused, sometimes even delirium. Very commonly the pulse is irregular, especially if the patient be young. At this stage again care must be taken to ascertain whether there are any asymmetrical symptoms—any weakness of a limb, of one side of the face, or of any single eye-muscle. If the patient passes his urine or fæces into the bed, or if there is any long-continued retention of urine, the case is not one of ordinary concussion. The sleepy stage may last for a day or for a week, and it is in severe cases so well-marked that the patient's eyelids may be held open and the pupils examined without awaking him. During this stage the measures of treatment called for are spare diet, purgation, cold to the head, and quiet. It may be necessary to use the nasal tube for feeding. When the sleepy stage passes off, the patient is left weary, torpid, unfit for mental effort, and often with distressing headache. This is the final stage of gradual *convalescence*, and its duration, before complete return to health ensues, varies greatly. Loss of memory, irritability of temper, and unusual susceptibility to alcoholic stimulation, are three results of severe concussion, which are the most constant and the most persistent. Loss of sexual power, homicidal or suicidal impulses, epileptiform fits, and true insanity are some of the graver and less common results of injuries to the head. But however long the patient may be incapacitated from work and however hopeless the condition may appear to be, a favourable prognosis may safely be given in the great majority of cases. Recovery from a condition of complete mental torpor, delirium, or even mania lasting several weeks has often been observed. On the other hand death may occur during the first stage, but in these fatal cases there is as a rule extensive damage to the brain associated with fracture of the skull. It is most important to remember that compression of the brain from meningeal hæmorrhage may supervene on concussion, and its symptoms be grafted on to those of the latter. The following symptoms should arouse suspicion:—(1) relapse into *complete* unconsciousness, from which the strongest stimuli will not rouse the patient; (2) stertor of breathing; (3) flushing of the surface, with a steadily rising temperature; (4) convulsive movements of the limbs followed by their paralysis; (5) fixed wide dilatation of the pupils (mydriasis).

TREATMENT.—During the stage of collapse there is but little required beyond assisting the circulation by the application of hot blankets to the skin. If the pulse be extremely feeble a subcutaneous injection of strychnine (gr. $\frac{3}{16}$) is better than the administration of alcohol.

After reaction has set in, a free action of the bowels should be obtained by giving 5–8 grains of calomel, followed by a saline draught. The room or bed should be darkened, and during the sleepy stage the patient should only be roused for purposes of feeding. The diet for some days should consist principally of fluids. Care should be taken that the bladder does not become over-distended, a point somewhat apt to be overlooked. To relieve

subsequent headache, and to diminish the irritability, often present in the third stage, cold to the head is most useful, and is best applied by means of iced-water running through Leiter's tubes, or pounded ice in an india-rubber cap, secured beneath the chin. Antipyrine, bromide of potassium, and sulphonal are sedatives worthy of trial in cases of very marked reaction or delirium. Constant watching may be necessary for many days or weeks after severe concussion, and it must be remembered that such cases are liable to violent outbursts if allowed to indulge in alcohol. The only safe course is total abstinence for long afterwards.

II. Compression.—The brain is compressed in the pathological sense whenever its structure is so squeezed that its functions are in any degree interfered with. This squeezing may be effected either by the effusion of blood within the skull, the growth of a tumour, the accumulation of pus or serum, or lastly by the depression of some large portion of the bony parietes. As already noted, a temporary compression occurs in many cases of ordinary concussion with or without fracture, but the general belief that depressed fractures are frequently the cause of compression is probably a mistake. In such cases the fragment displaced is rarely of sufficient size to cause serious compression of the contents of the skull, and the symptoms usually supposed to indicate that state are really due in most cases to laceration and contusion, or to subsequent inflammation.

By far the best examples of uncomplicated compression of brain are supplied to us by the not very infrequent cases in which one middle meningeal artery is injured, and a large blood-clot is effused between the dura mater and bone. It is from observation of cases of this kind that the assertion is justified, that a very considerable intrusion into the skull may be permitted without the production of any symptoms. No doubt the suddenness or otherwise has much to do with the results, but there seems good reason to believe that, as a rule, the brain will easily accommodate itself to quantities not exceeding an ounce or two, and that usually as large a quantity as four or five ounces is required to cause death. It is very rarely indeed that a depression of bone in the least approaches such an extent of intrusion as this, and the majority of such cases are, as regards the amount of possible squeezing, quite trivial. The manner in which the accommodation is effected is by the removal of the fluid contents of the skull—first the subarachnoid fluid, and secondly the blood. Of the blood-vessels the veins and venous sinuses are probably emptied first, and lastly the arteries and capillaries. A brain in a state of strong compression is an exsanguine brain. In this respect, the brain in the last stage of compression differs very much from that in cases of insensibility from concussion or contusion. It by no means follows that because the brain is pale the face should be pale also; but it is perhaps usually the case that extreme compression so much enfeebles the heart's action that the pulse is weak or flickering, the respiration shallow and irregular, and the skin pale and cold. That stertorous breathing, a laboured pulse, and a suffused and dusky countenance are (as according to the classical description) symptoms of compression, is probably for the majority of cases a mistake. Such a group much more frequently denotes laceration, contusion, or central extravasation. Nor is it true that hemiplegia, excepting of the most transitory kind, is often due to compression.

A clot of blood poured out over one hemisphere may, if rapidly effused, produce for a while weakness of the opposite limbs, but the brain-mass is soft enough to allow of considerable yielding, and in the course of a few hours the effects of the displacement will have become general, and not local. In a case recorded by the writers in which a *post-mortem* examination, some weeks later, proved the presence of a large blood-clot, there had been partial hemiplegia without unconsciousness at first, but on the next day all trace of it had disappeared, and it never returned. In many of the cases of bleeding between the dura mater and the bone, from the meningeal artery, the hæmorrhage takes place on several different occasions, with, it may be, intervals of a day or two, much as is often observed in wounds of arteries, such as the palmar arch. Thus, the observer is able to appreciate the symptoms caused by different degrees of compression, and further proof is afforded that, if the intruded quantity be but moderate, the brain bears it without obvious inconvenience. Often at the autopsy it is quite easy to distinguish clots of very different dates, and to feel sure that the original one was of considerable size. It is clear then that in speaking of the symptoms of compression we must allow for differences in amount of the compressing substance, and also for differences in the rapidity or suddenness of its application.

When compression is produced suddenly, as by a large fragment of bone driven down, the case is almost invariably complicated by contusion. If paralysis or even insensibility be present, it is usually impossible to say to which lesion they are really due. We may, however, hold it almost certain, from what we know of other cases, that the effects in such would be a temporary hemiplegia, with symptoms of shock, if the depression were but moderate; and insensibility, probably soon followed by death, if the depression were very great. The cases in which depression of bone has alone been sufficient to produce long-continued compression with insensibility are possibly somewhat apocryphal. It is possible that compression under such circumstances might be attended by stertor and laboured pulse, but it is possible also that the pulse might be extremely feeble, the countenance pale, and inspiratory efforts weak and irregular.

The depression of bone is perhaps the only condition which can be supposed capable of producing compression suddenly. When blood is poured out from a ruptured artery, the symptoms come on rather gradually. The patient complains perhaps of headache, and then becomes more or less confused in manner, his gait is unsteady, and the limbs on the side opposite to the injury show special weakness. Vomiting may occur and the weakened limbs may twitch, and unless, as is often the case, the intracranial bleeding stops, these symptoms are soon lost in a state of complete insensibility, with pale face, feeble pulse, and symptoms of shock. Convulsions may now occur, and death often supervenes very quickly. In such a case the whole course of the symptoms may occupy less than an hour. The surgeon ought, of course, to trephine and let out the blood, and he must be prompt, or his patient may die during his preparations. More commonly this rapid termination occurs unexpectedly after one or more previous attacks of temporary head-symptoms, and the patient may have appeared quite well in the intervals. In cases in which the symptoms progress without interruption, their rapi-

dity, no doubt, depends upon the size of the vessel ruptured. Certain special symptoms will also depend upon the precise position taken up by the clot, which may chance to press upon special nerve-trunks as well as upon the brain-mass. In ordinary cases the clot is beneath the squamous bone and the lower part of the parietal, and passes downwards into the middle fossa. In the latter region it may press upon the nerves going to the sphenoidal fissure; and it is of importance for the surgeon to know that dilatation of the pupil on the affected side is often produced. This important symptom is probably due to pressure upon the third nerve.

There is yet another class of cases of compression in which that condition is produced by the slow accumulation of the products of inflammation within the skull. Much will depend, as regards special symptoms, upon the position of the abscess, either within or without the brain. If in the substance of the brain, it must more or less disorganise its structure, and thus cause symptoms due to laceration as well as compression. Under such conditions some degree of hemiplegia, with, probably, preceding spasms of limbs, can scarcely fail to be present. Now and then cases occur in which an irregular sinus leads into an abscess-cavity in the brain, and this sinus being sometimes free and sometimes blocked, the surgeon has repeated opportunity of estimating the effects of filling of the cavity. In such cases, headache, stupor, unilateral twitching of limbs, partial hemiplegia, with perhaps vomiting and, it may be, general convulsions, are the symptoms to be expected. The position of the abscess as regards different regions of the brain is also of much importance, but its discussion cannot be entered upon in any detail here, and it obviously concerns rather disorganisation of structure than simple compression. In one case, seen by the writers, epileptic convulsions, repeated so frequently as to be almost continuous and accompanied by complete unconsciousness, were cured by trephining and letting out a quantity of clear fluid which had existed under high tension in the substance of the brain. The condition had apparently resulted from old injury to the head.

When a large accumulation of pus takes place between the bone and dura mater, the symptoms produced are much the same as those caused by blood-clot. We must make, however, much allowance for the fact that these cases are almost always attended by meningitis, and thus the symptoms of compression are masked by those due to inflammation. Chronic abscess under the bone without arachnitis may occur now and then in syphilitic and other disease of the cranial bones, but such cases are very rare. They will differ from those of hæmorrhage in that the symptoms are always produced very slowly. The writers once had the opportunity of watching such a case, in which the patient died of compression, very gradually produced by an increasing collection of pus between the bone and dura mater, and without any complication. The chief symptom was constant wearing headache, which prevented sleep. The man was pale and feeble, but not paralysed in any part, excepting that both eyelids drooped. He was rational, but spoke slowly, as if in a state of partial stupor. During the last two or three days of life he had convulsions; and finally, for twenty-four hours, he was in a state of increasing insensibility.

DIAGNOSIS.—It will be seen from what has been said above that the diagnosis of compression by symptoms is exceedingly difficult, and that the utmost use must be made of the history in each individual case. In those of compression by blood after injury to a meningeal artery, there is almost always the fact that the patient, between the date of the injury and the supervention of symptoms, had an interval during which there appeared to be little the matter, or in which the ordinary symptoms of concussion were present. This history is, if the symptoms have developed rapidly and without the signs of inflammation, by itself conclusive for diagnosis. The pupils become widely dilated, and do not respond to light. The pupil on the side of the hæmorrhage is first and most affected. The limbs become first convulsed and then paralysed, those on the opposite side to the hæmorrhage are first and most affected. Under such conditions trephining ought to be at once resorted to. A trephine of at least one inch diameter should be applied over the anterior branch of the middle meningeal artery (on the side indicated by the above rules). If no extravasation is found between the dura mater and bone, the former should be incised and any clot on the surface of the brain gently removed. In rare cases the posterior branch of the meningeal is torn, necessitating the opening being made through the posterior part of the parietal bone.

The diagnosis of abscess in the brain-substance is discussed elsewhere. See BRAIN AND MENINGES, Septic Diseases of.

BRAIN, Œdema of.—**DEFINITION.**—Infiltration of the brain and pia mater with serum.

ÆTIOLOGY AND PATHOLOGY.—In chronic maladies attended with general œdema, especially Bright's disease, there is an increased amount of fluid around the brain—in the meshes of the pia mater and between the convolutions—and also in the ventricles. Occasionally the cerebral substance is infiltrated; but this is uncommon, and it probably occurs only when there is some change in the cerebral structure. The perivascular canals normally afford a ready means of escape for effused serum, and in Bright's disease, at least, the substance of the brain is often remarkably firm, so as to present a contrast to the condition of other organs. But apart from any general disease, all spaces that result from a diminution in the volume of the structures within the skull are filled by serum. Thus in senile atrophy of the brain, the space between the sunken convolutions is occupied by serum, and the ventricles contain an excess of fluid. The brain-tissue may also appear to contain more fluid than usual, in consequence of the presence of serum in the enlarged

perivascular canals. Such effusion is also met with in those forms of insanity in which there are degenerative changes in the brain with a diminution in its volume. It is seen also in cases of rapid course, in which functional excitement is attended with some vascular disturbance. Conditions of hyperæmia and inflammation are attended with effusion of serum in the brain, as in other organs, and it is in cases of inflammation that the greatest amount of œdema is met with, but this condition is not included in the common use of the name. In passive congestion, however, such as results from heart-disease, enough serum may escape from the distended vessels to give rise to a condition of œdema; but it is probable that when the excess is more than trifling, room is made for it by wasting of the nerve-elements, the result of the continued pressure to which they are exposed.

When the degree of œdema is considerable, the cerebral substance may be enlarged, the convolutions being flattened; and the tissue is lessened in consistence owing to the infiltration of the cerebral tissue by the liquid, and the separation by it of the nerve-elements. A microscopical section shows empty round and oval spaces between the cells and fibres, limited by delicate tracts of the separated neuroglial tissue. Similar softening is seen in the neighbourhood of effusions of fluid into the ventricles; the brain-tissue, for a depth of some lines from the ependyma, being softened to a pulpy consistence. *Post-mortem* imbibition always increases the apparent amount of the œdema and the degree of the softening, because the nerve-elements quickly begin to break up after death. In simple œdema the tissue remains pale, and the grey substance may be paler than usual.

SYMPTOMS.—Little is known of the symptoms of œdema of the brain. The pathological state is usually secondary to some other condition, the symptoms of which mask any that the œdema itself may possibly cause. General œdema seems attended by slow diminution of mental power and motor force, which may be in part due to it, but has other possible causes in most cases. The effusion of serum in congestion, and consequent pressure on the nerve-elements, has been considered as the cause of the symptoms of depression common in that condition. Cases occasionally occur in which effusion of serum into the ventricles and the pia mater is the only *post-mortem* condition to be found after an apoplectic seizure, and such cases are often spoken of as instances of *serous apoplexy*. See APOPLEXY, CEREBRAL.

TREATMENT.—The treatment of cerebral œdema is usually secondary to the condition, commonly conspicuous enough, which is its cause—Bright's disease, passive cerebral congestion, &c. If œdema be suspected where no causal indication for treatment exists, purgatives and diuretics, with iron if there be debility, are the remedies most likely to be of service. But where a diagnosis is speculative, treatment necessarily lacks a confident basis.

The effusion of fluid into the ventricles is described under HYDROCEPHALUS.

BRAIN, Sclerosis of.—See SPINAL CORD, Special Diseases of: Multiple Sclerosis.

BRAIN AND MENINGES, Septic Diseases of.—It is impossible to draw any line of demarcation between a septic inflammation, whether

general or localised, originating on the surface of the brain internal to the dura mater, and a similar inflammation originating in the substance of the brain. In all cases these inflammatory affections are caused by the introduction of septic micro-organisms. The same micro-organism may cause an abscess to originate on the surface, or may commence its action deep in the cerebral mass. The same predisposing cause, e.g. chronic purulent otitis media, may cause an inflammation on the surface, diffused or localised, with or without the formation of pus. It may also be the predisposing cause of a deep cerebral abscess—indeed, the two conditions may be and often are present at the same time.

Pathologically, no line of demarcation can be drawn, since the ordinary form of diffused septic inflammation affecting the arachnoid and pia mater or *septic lepto-meningitis* is always associated with more or less inflammation of the tissue of the brain, commencing on the surface where the vessels enter from the dura mater, and gradually spreading inwards so that lepto-meningitis and encephalitis are always present together. In a similar way, if the inflammation is localised an abscess may form on the surface, invading to a greater or less extent the brain-substance.

For practical clinical work it is most important that these points should be thoroughly appreciated. It is disappointing at first to think that the differential diagnosis between an abscess on the surface and an abscess deep in the substance of the brain is very uncertain, yet experience shows that even moderate certitude is impossible.

ÆTIOLOGY AND PATHOLOGY.—It is obvious that, in certain injuries of the head and brain, septic micro-organisms enter the meninges, or substance of the brain, or both, at the moment the injury is inflicted. These may give rise to primary encephalitis or meningitis. In certain cases of injury and in some cases of disease the organisms reach the area of their operations in an indirect, and sometimes by an unknown route. Thus are produced secondary encephalitis and meningitis.

The organisms may reach the brain and meninges by several routes. The direction of their line of march is sometimes clearly evident; in other cases the route is rather hypothetical. Where the organisms are introduced as the result of injury or of disease, they generally take one of the following routes: (1) By direct extension from the region of the scalp or skull, or both. The dura mater is a good barrier against septic infection of the meninges, but in some cases it is unable to resist the growth of germs, and so we may get either local lepto-meningo-encephalitis, or an abscess upon or in the brain, or a general lepto-meningo-encephalitis. (2) By the venous system: infection may take place by progressive thrombosis, or by a process known as 'reflex propagation', owing to a thrombus causing a reversal of the blood-stream, which may sweep organisms towards a certain region. (3) By the perivascular lymphatic sheaths of the arteries. (4) By an anastomosing lymphatic space. Thus germs may pass from the galea to the subdural space, as in erysipelas of the scalp. (5) By perineural lymphatics, such as those communicating with the sub-arachnoid space. (6) By metastatic infection, the primary septic focus being in the head or some other part of the body, i.e. ordinary pyæmic infection.

I. Diffused Septic Inflammation (*septic meningo-encephalitis*).

PATHOLOGY.—The earliest change is intense hyperæmia with punctiform hæmorrhages in the pia mater, the vascularity of which becomes very evident. Very soon the inflammatory exudation is poured into the subarachnoid space and increases the amount of subarachnoid fluid and consequently alters the character of the cerebro-spinal fluid. The exudation, clear at first, soon becomes red, and finally turbid owing to the presence of leucocytes. This condition may increase so that there is definite pus and flakes of lymph are deposited upon the pia mater and arachnoid. The inflammatory process extends into the cortex of the brain, which becomes softer than normal and oedematous. Under the microscope the inflammatory process can be seen extending from the pia mater into the cortex along the periarterial lymphatic sheaths. In injuries of the skull the inflammation usually commences in the region of the fracture, either on the vault of the skull or on the base; so clinically two forms of lepto-meningitis are found, viz. of the convexity and of the base. In disease the basal form is by far the more common, owing to the great frequency of complications from chronic suppurative otitis media.

SYMPTOMS.—The onset is usually indistinguishable from that of any acute septic disease—headache, fever, shivering, or even rigors. This stage lasts from a few hours to 24 hours.

Stage of irritation.—The patient becomes very restless and often delirious. The pain in the head increases and may become distressing. There is marked photophobia and intolerance of noise. The pupils are equal and contracted, reacting to light. Optic neuritis usually commences in this stage. Convulsions are not constant in their appearance, and when present vary both in degree and distribution. As the convulsions recur the muscles concerned become progressively weaker; the patient becomes more and more drowsy and finally insensible. During this period the pupils begin to dilate, as a rule unequally, and their reaction to light is slight or absent.

Stage of paralysis.—Convulsions, if present, cease and the muscles become paralysed. The paralysis sets in even if no convulsions have occurred, and may vary in extent from a small group of muscles to hemiplegia, or complete muscular paralysis. The patient lies insensible and motionless and the respirations are accompanied with marked stertor. This comatose condition varies in duration from one to two or three days, and the patient usually dies within a week of the onset of the disease. The pupils become widely dilated on both sides and are insensible to light. The pulse is quick and bounding at first, and as the compression increases it becomes slower, only to increase again and gradually weaken during the final stage. The respirations are regular and deep at first, become rapid and superficial in the final stage, and cease before the heart stops. The temperature as a rule is raised, varying from 101° to 104° and rising to 106° F. towards death. Sometimes it is scarcely raised at all, and may even be subnormal.

DIAGNOSIS.—At the onset this is impossible, unless there are reasons for suspecting its occurrence. For the differential diagnosis from the effects of contusions or lacerations of the brain, see BRAIN, Injuries of. Differences in the symptoms may help

us in distinguishing meningitis of the convexity from meningitis of the base. In *basal meningitis* (a) retraction of the head and rigidity of its extensor muscles come on early, and are fairly characteristic; (b) optic neuritis is more constant in its presence, is more intense, and comes on earlier; (c) squint from spasm, or paralysis of one or more of the ocular muscles, is usually an early and characteristic symptom. In *convexity-meningitis* (a) convulsions come on earlier, and are more frequent; (b) the convulsions are more likely to be localised at first to definite groups of muscles.

PROGNOSIS AND TREATMENT.—It is probable that no case of diffused septic meningo-encephalitis has recovered. No treatment, medical or surgical, appears to have any definite influence upon the course of the disease. Draining the subarachnoid space has been tried several times without success.

II. Cerebral Abscess.—**ÆTIOLOGY.**—All abscesses of the brain are caused by micro-organisms, but in many cases it is impossible to state the exact path by which the germs reach the particular region of brain-substance affected. This question has already been discussed at the commencement of the article. The causes of cerebral abscess are: (1) *Chronic purulent otitis media* is by far the most common cause, and the resulting abscess is situated generally either in the temporo-sphenoidal lobe or in the cerebellum. An abscess is rather more frequent on the right side than on the left. Abscess in the cerebrum from this cause is about four times as frequent as in the cerebellum. (2) *Injuries of the head* may be followed by abscess of the brain, which is most common in the frontal and parietal regions. (3) *Disease of the cranial bones*, usually syphilitic or tubercular, is a rather uncommon cause. Necrosis of the upper jaw from phosphorus-poisoning has been known to cause cerebral abscess. (4) *Pyæmic* abscesses may occur in the brain and are usually multiple. Empyema and bronchiectasis form the most common primary foci.

PATHOLOGY.—The abscess may be a very acute one, with no distinguishing wall demarcating it from the surrounding cerebral substance. These are generally caused by septic infection from a punctured wound. As a rule the ordinary cerebral abscess, e.g. the one secondary to chronic purulent otitis media, forms gradually and has a very definite wall or capsule which definitely separates it from the surrounding brain-tissue. In such cases the pus often smells offensively. The abscess may remain in a quiescent state for quite a long time and may then suddenly increase in size, causing rapidly progressing symptoms. In some cases the abscess bursts into the ventricles of the brain, or on to the surface, causing a suppurative lepto-meningitis. In rare cases the pus may be discharged to the exterior, either into the ear by perforating the tegmen tympani or through an erosion in the temporal bone.

SYMPTOMS.—(1) *Acute cerebral abscess.*—The symptoms of this are sometimes very similar to those of meningitis; in fact lepto-meningitis is usually present at the same time. Intense headache with high temperature associated with rigors is rapidly followed by symptoms of cerebral compression, and the patient dies in a comatose condition within from one to three weeks of the onset.

(2) *Chronic cerebral abscess.*—In this case there are well-recognised general symptoms, caused chiefly by the increased cerebral pressure: they are often present in conditions causing such pressure apart from the abscess. These symptoms are:—

Persistent headache, often most distressing and limited to one side of the head, soon accompanied by drowsiness. The onset of optic neuritis is usually early and should be carefully looked for. It may be absent altogether or develop late in the progress of the disease. The temperature is characteristically subnormal, with an occasional sudden rise to 104°, often accompanied by a rigor. Vomiting is generally present.

In addition to these general symptoms there may be others which may aid us in localising the abscess. Such localising symptoms are not always present, and in these cases the patient may die with the general symptoms only. The local symptoms depend upon the situation of the abscess.

(a) *Abscess in the temporo-sphenoidal lobe*, by exerting pressure upon the internal capsule, may cause paresis or paralysis of the whole or a part of the opposite side of the body. If on the left side it may lead to disturbance of speech.

(b) *Abscess in the cerebellum* is usually accompanied by very intense optic neuritis, and the vomiting is usually persistent and distressing. In the early stage inco-ordination of the patient's gait is characteristic. Later on retraction of the head and symptoms indicating unusually severe pressure upon the medulla oblongata, such as slow pulse and respiration, are usually present. Cases have been recorded in which there was paralysis of the muscles of the same side of the body as the abscess in the cerebellum.

(c) *Abscess in the sensori-motor area* is shown by the presence of convulsions, or of localised paralysis according to the exact situation of the lesion.

DIAGNOSIS.—The diagnosis of abscess of the brain is often a matter of extreme difficulty. On the one hand we have to distinguish it from the other septic diseases of the brain and its meninges, and, on the other, from tumours of the brain, especially in the case of the chronic abscesses which may closely resemble the former in their clinical features. In addition to this we have to bear in mind the possibility of phlebitis of the lateral sinus being confused with cerebral abscess: indeed, it is occasionally present at the same time. *Headache* and *vomiting* vary so much in character and in degree that they often afford but little help in the diagnosis, e.g. a very localised headache may be present both in the case of abscess of the brain and in thrombosis of the lateral sinus; on the other hand, in both of these conditions the headache may be quite diffused. *Vomiting*, too, aids us but little in the diagnosis excepting when its unusual violence leads us to suspect an abscess in the cerebellum. *Optic Neuritis* is never present in uncomplicated phlebitis of the lateral sinus. It is usually present in abscess of the brain and can be looked upon as a most important diagnostic symptom. This symptom is usually present in meningo-encephalitis, but the patient usually dies before the condition becomes at all marked. The pulse when very slow is in favour of a cerebral abscess; if very rapid and very weak, phlebitis of the sinus is more probable. A subnormal tempera-

ture is in favour of abscess of the brain, whereas a markedly remittent one rather indicates sinus-thrombosis. As far as these general symptoms are concerned, they aid us but little, if at all, in diagnosing between a marked cerebral abscess and a tumour of the brain. To diagnose between these two conditions it is most important to look for any predisposing cause, such as a previous injury or the existence of chronic suppuration in the neighbourhood of the cranium, whether in the ear, nose, or other region.

PROGNOSIS.—If the pus be not evacuated the prognosis is most serious, nearly every case ending fatally. With prompt surgical interference the results are extraordinarily good, e.g. MacEwen reports 18 recoveries out of 19 cases.

TREATMENT.—This is of course purely surgical. As soon as the presence of pus is suspected an attempt should be made to evacuate it. When the situation of the pus is indicated with reasonable certainty, the opening in the skull should be made as nearly as possible directly over the abscess. When in the temporo-sphenoidal lobe, the pus is usually found in that part of the lobe adjacent to the tegmen tympani. The best spot for the centre of the opening in the bone is a point a quarter of an inch behind, and three quarters of an inch above, the centre of the external auditory meatus. When in the cerebellum, the centre of the opening should be one and a half inches behind, and a quarter of an inch below, the centre of the external auditory meatus. When the abscess is thought to be in other parts of the brain an opening should be made over the most likely spot. In cutting a flap of scalp one must bear in mind that it may be necessary to enlarge considerably the opening in the bone some distance from the original one; hence the scalp-flap should be of sufficient size to allow for such a contingency. When the presence of pus in the brain is fairly certain, but when there are no indications concerning its position, the operator must be prepared to search in every likely spot. Fortunately in the great majority of cases the pus can be reached by one scalp flap and one opening in the bone. The operation performed by the writer is as follows: A suitable semicircular scalp-flap having been made, the bone is perforated by a trephine-drill or other suitable instrument at a spot one and a quarter inches behind and a quarter of an inch above the centre of the external auditory meatus. By this means the lateral sinus, just as it begins its downward turn, is exposed together with the dura mater above and below it. By enlarging the bone opening upwards, so as to obtain sufficient room above the lateral sinus, and by incising the dura mater the temporo-sphenoidal lobe can be thoroughly explored with a trocar. In a similar way, by enlarging the opening in the bone downwards, the cerebellum can be equally well explored. If no pus is found in these situations, it is quite likely that the inflammation is a diffused one, i.e. a meningitis. In these cases the pressure can be easily reduced temporarily by inserting a trocar inwards and slightly upwards immediately above the lateral sinus so as to enter the descending cornu of the dilated ventricles. The writer has left a drainage tube in the ventricles in such cases, but with no permanent benefit. The condition of the lateral sinus can readily be ascertained during the removal of the bone. The mastoid emissary vein may be seen. If this is thrombosed it will

generally be found that the sinus is plugged also. After exposing the sinus any doubt on this score can be dispelled by inserting a small trocar into it. The operation can be completed in thirty minutes or less, and the operator will seldom fail in finding pus, if any be present in that region.

HENRY PERCY DEAN.

BRAIN, Softening of.—**DEFINITION.**—A pathological state of brain-tissue, attended by diminished consistence; usually local; and indicated, during life, by mental, motor, and sensory symptoms, which vary according to the seat of the lesion. It is produced rapidly in the vast majority of cases, and is then almost always dependent on vascular obstruction. Very rarely it is chronic in development, and the nature of the actual process is not known. The following description applies to the acute form.

ÆTIOLOGY.—Acute softening of the brain, occurring during life, and not due to a traumatic cause, is referable to one of two conditions, inflammation or vascular obstruction. Most cases were formerly thought to be due to inflammation; but it is now known that very few are. Inflammatory softening is described in another article (*see* BRAIN AND MENINGES, Septic Diseases of). The vascular obstruction, which is the usual cause of softening, may be arterial or, rarely, capillary. Venous obstruction also causes softening, but the loss of consistence does not involve the whole of the tissue of the part, and enough remains to permit an ultimate restoration of firm tissue and even the production of induration. The arterial obstruction may be due to thrombosis, or to embolism (*see* BRAIN, Vessels of, Diseases of; EMBOLISM; THROMBOSIS). The common concomitant conditions are—in thrombosis, arterial disease; in embolism, valvular disease of the heart; and as predisposing conditions we usually find—in cases of thrombosis, advanced age, Bright's disease, chronic alcoholism, gout, or especially in earlier life, syphilis;—in cases of embolism, acute rheumatism, chorea, or scarlet fever. Senile vascular degeneration is the most common cause of thrombotic softening, and hence the disease is met with most frequently in the old. In rare cases, thrombosis occurs without disease of the vessels, from a state of the blood alone. It is probable that this is sometimes a cause of hemiplegia coming on a few days after child-birth, when there seems to be a physiological increase in the coagulability of the blood. Embolism, due to valvular disease of the heart, and thrombosis due to syphilitic disease, are the most frequent causes of acute local softening in the young and middle-aged.

ANATOMICAL CHARACTERS.—The characteristic feature of cerebral softening is diminished consistence. This may, however, arise from either *ante-mortem* or *post-mortem* changes. In each case the diminished consistence depends on the breaking-up of the material of which the nerve-elements are composed into globules and granules, and the separation of these by an increased quantity of fluid. Thus the continuous structures of which the brain consists are broken up into disconnected fragments, and the consistence of the tissue is accordingly diminished. In *post-mortem* softening there is nothing more. The globules of myelin are often large, and the separating fluid abundant. The softened tissue has the tint of the normal

cerebral substance. The process is the result of the imbibition of fluid from some collection of serum, in the ventricles or elsewhere, and occurs in the greatest degree in the immediate vicinity of this. In *ante-mortem* softening there are, in addition, certain changes in the tissue-elements. The process of segmentation of myelin results in the formation of finer granules. These are in part aggregated into round or oval masses of globules and granules, sometimes contained within a distinct cell-wall. Some of these bodies may arise by simple aggregation, others by the aggregation of products of nerve-degeneration within cellular elements of various kinds. The walls of vessels in the softened area also present fatty degeneration. No further change may exist, and the area affected may present simply a diminution of consistence, its colour remaining unchanged. It is then called *white* or *grey softening*. Very frequently, however, in the part thus diseased, distension of capillaries with blood occurs, most considerably in the periphery, in consequence of the arrest of circulation and strain on the vessels, and blood is actually effused, chiefly by rupture of capillaries, in trifling degree perhaps by diapedesis of corpuscles. In proportion to the amount of blood mingled with the softened brain-tissue, the colour of the affected area is changed, and thus *red softening* is produced when the amount of blood is considerable. In the change which results from closure of a vein, the tissue is crammed with punctiform extravasations, and a purplish colour results; but, as already stated, there is not the general diminution of consistence that brings the alteration into the category of 'softenings.' After a time, the blood effused in red softening degenerates, its tint becomes altered to yellow or orange, and *yellow softening* is found. Ultimately, it is said, the colour, if at first moderate, may be removed and white softening result, but the pigment that gives rise to the yellow tint may remain for many years.

Red softening is found chiefly in the grey substance, where the vessels are numerous, especially in the cortex and central ganglia. The tint varies; the red colour is usually punctiform, or mingled with yellow and white. According to the amount of effusion of serum and blood there is swelling, and the diseased area may project above the cut surface. Inflammatory changes result from the vascular distension, and in proportion to these, increase in the nuclei of the neuroglia is found, especially at the circumferential portions. From this cause, and from the migration of white-corpuscles, pus-like cells appear among the products of degeneration in varying quantity. The vessels are dilated, and may present a moniliform appearance. Their perivascular sheaths are often distended with blood.

Yellow softening results from red softening, by degenerative changes in the blood effused attended by a change in its pigment. It has a similar seat, being frequently met with in the convolutions, where it constitutes the *plaques jaunes* of the French. Its consistence is usually slight, its aspect granular. The colour depends on the presence of minute pigment-granules, diffused colouring matter, and hæmatoidin-crystals.

White softening has the tint of the normal cerebral substance. In consistence it varies: it may be only a little below that of the cerebral substance, or it may be diffuent. Its aspect is

uniform, or white flakes are scattered through it. The limits are usually gradual. Under the microscope it presents the detritus of nerve-elements and connective tissue, and, ultimately, corpora amylacea. White softening is chiefly found in the white substance of the hemispheres. It occasionally has a gangrenous odour, and then may be found in the white or in the grey substance; probably this form results from the obstruction of capillaries by septic material. It is theoretically probable that when softening is white from the first, the capillaries are the seat of the primary obstruction. It occurs also in the zone of cerebral tissue in which meet the regions supplied by the arteries of the cortex and of the central ganglia.

Ultimate changes.—White and yellow softening may remain for years unchanged. Usually the products of disintegration of the nerve-elements are gradually removed, so that a cavity remains, across which bands and trabeculae pass—the remains of vessels and other structures that have escaped total necrosis. Sometimes the changes in the elements of the neuroglia and the extravasated white corpuscles result in the formation of a considerable quantity of connective tissue, consisting of fine fibre-cells and fibres, most abundant in the margins of the softened areas, which become firm and dense, while the trabeculae of the connective tissue, crossing the cavity, are thickened in like manner. After a time when the amount of this tissue is considerable, the fluid may be absorbed, and a sort of cicatrix result from the union, partial or complete, of the walls. In other cases the walls alone are thus altered, the solid particles are removed from the softened tissue, and a cyst is formed. The outer portion of the cyst or cicatrix may be limited by a zone of dilated blood-vessels, presenting, under the microscope, a peculiar and quite characteristic feature.

Seats of softening.—There is no part of the brain in which softening has not been found, but its most frequent seats are the cortex, the corpus striatum, and the optic thalamus. In the pons Varolii and medulla it is also frequently found, but it is rare in the cerebellum. Its frequency in the medulla is underrated because only minute areas of softening are compatible with a duration of life sufficient to permit them to assume a characteristic aspect. Its occurrence, position, and characters depend on the distribution of the vessels. The small arteries of the corpus striatum and optic thalamus are 'terminal arteries,' having only capillary communication with other vessels, insufficient for a collateral circulation adequate to maintain the vitality of the tissue. The arteries to the cortex of the brain are sometimes terminal, but sometimes possess anastomosis by arterioles with other branches. Hence obstruction in the central arteries leads invariably to softening, while obstruction in the superficial arteries may also cause softening (which involves the grey substance of the convolutions and some of the subjacent white centre to which the vessels penetrate), but often the anastomoses of the superficial vessels are so free that softening does not result. An obstruction of a main trunk (as the middle cerebral) may lead to softening of the central region (corpus striatum), while the convolutions escape; but usually both suffer. For the same reason, the softening of the cortex is apt to be irregular in distribution, and partial even within the region of the obstructed artery, a feature considered

further in the article on Diseases of the Vessels of the BRAIN.

SYMPTOMS.—The *premonitory* symptoms of softening of the brain depend upon its mechanism, and are considered in greater detail in the articles describing its causes. In embolism other symptoms than those of cardiac disease are usually absent. Occasionally a slight attack of loss of cerebral function, due to a slight embolism, may precede a graver attack. In softening due to arterial disease, premonitory symptoms of local cerebral anæmia are frequently present; these may exist for months before the onset, or only for a few days, or even for a few hours. There is also, in many cases, sufficient disease to impair the nutrition of many parts of the brain, revealed by symptoms of wide range—mental deterioration, numbness, and pains in the limbs, pain in the head, or slight local weakness. These symptoms are of especial significance when associated with evidence of degeneration elsewhere in the arteries; with the conditions—as chronic Bright's disease, alcoholism, and senility—in which atheroma of the cerebral arteries is common; or with constitutional syphilis. Such slight cerebral symptoms may also precede the softening due to syphilitic arterial disease, but the most common antecedent of this is headache for a week or two, often considerable.

The symptoms of *actual* softening are those of loss of function in the damaged portion of the brain. Strictly, indeed, these symptoms are those of the anæmia that causes the softening, and which, depriving the brain-tissue of the material for its functional action, arrests the latter with rapidity. The onset of the symptoms may be actually sudden, as in embolism, and sometimes in thrombosis; or it may be gradual, as occasionally in thrombosis, and less commonly in embolism. When sudden, the symptoms of initial shock are added to those due to the structures involved (*see* BRAIN, Tumours of). Hemiplegic symptoms and mental disorder are the most common effects. Hemiplegia especially occurs in embolism, on account of the frequency with which the middle cerebral artery is obstructed, and of the important motor regions (corpus striatum and motor parts of the convolutions) to which that artery is distributed. From the distribution of the artery to the lower frontal convolutions and adjacent region, aphasia is frequently present when the obstruction is on the left side. Hemianæsthesia is also common, and also hemianopia, which often escapes detection.

When the onset is sudden it is often after some fatiguing exertion, or during exhaustion from any cause, or in embolism after some cause of undue excitement of the heart's action. If the area damaged be extensive, there is loss of consciousness, and there may be all the symptoms of an apoplectic seizure. The loss of consciousness is rarely profound, and the symptoms of apoplexy soon pass off. In the most severe cases, however, they may deepen to fatal coma, especially when an important artery is occluded in each hemisphere. Thus the closure of both middle cerebral arteries causes symptoms indistinguishable from those of ventricular hæmorrhage and equally fatal in ultimate result. Symptoms of irritation commonly succeed the onset as the collateral hyperæmia sets in, or they may be marked from the first. Convulsions, usually unilateral, may occur and be repeated for days, chiefly when the softening involves the motor region of the cortex, and spares the path from it through the central ganglia. Convul-

sions may also occur in a few weeks or during the stage of secondary inflammation which occurs from the third to the seventh day after the onset, and is usually attended by slight pyrexia, some pain in the head, and occasionally some delirium. The patient may even pass from the apoplectic condition into one of delirium. In the aged, delirium may be the chief symptom of the onset in cases in which the softened areas are small, multiple, and cortical in situation. According as these symptoms are chiefly marked at the onset three varieties have been described, the *apoplectic*, *convulsive*, and *delirious* forms.

Recovery from the special symptoms of the attack is often incomplete; permanent weakness may remain, as hemiplegia, and mental power is lessened in the old, the patient passing into the chronic state about to be described. The persistent hemiplegia is often accompanied by rigidity, or, when the loss of power is incomplete, by mobile spasm, such as, in its most marked form, has been described as *athetosis*. When the cause is arterial degeneration, return or relapse is common, and it is almost invariable where senile arterial disease is widely spread.

Chronic softening of the brain is a term applied to a group of symptoms, of wide range, indicative of failure of cerebral power. It is a term that has become firmly rooted in popular nosology, where it denotes chiefly general paralysis of the insane, but includes also all maladies attended by a similar mental failure, profound in degree, permanent in duration, and progressive in course. The symptoms indicated by the term may supervene on more acute symptoms of softening, or may be gradual in their onset. There is mental dulness, defective perception, drowsiness, loss of memory (especially for recent events), often slight wandering; emotional manifestations are easily excited. Physical power is defective—as a rule generally, sometimes locally. The more delicate motor actions are imperfectly adjusted: articulation becomes indistinct, and the handwriting imperfect. These symptoms may progress into actual imbecility, or may be cut short by some more profound cerebral seizure, or by some intercurrent pulmonary affection, rendered grave by the deficient muscular respiratory power. They are met with chiefly in the aged, and are probably due to concomitant degeneration of cerebral tissue and of the arteries supplying it with blood—the two pathological elements varying in relative degree and in relation. Spots of softening, often widely spread, may be found, and are, indeed, the cause of many of the symptoms. But the state may also come on without any local softening, and without the degeneration of vessels to which such softening is usually due. A similar state often follows any grave local lesion of the brain in advanced life.

Progressive symptoms, local or general, or both, sometimes of the character just described, and sometimes such as are caused by a cerebral tumour, have been met with in a few cases in which extensive local softening of the cerebral tissue has been found without vascular disease to explain it, and without correspondence with arterial territories. Most subjects have been old, and the disease has not commonly been diagnosed during life. Some patients with well-marked symptoms of this character have been the subjects of strong constitutional gout, and it has been conjectured that a local gouty inflammation of the cortex has been the cause.

DIAGNOSIS.—The *acute* form of softening has to be distinguished from acute congestive apoplexy and

from cerebral hæmorrhage. It is distinguished from the former by the occurrence of the symptoms indicative of local mischief, and by the absence of evidence of cephalic hyperæmia. From hæmorrhage the diagnosis is often difficult, except during the first half of life, when hæmorrhage is so rare that it should only be thought of when loss of consciousness is profound and prolonged. In softening from thrombosis, the initial apoplectic symptoms may be absent, or, if present, they are slight and brief. They are more often preceded by slight local cerebral symptoms, due to the vascular disease, than is the onset of cerebral hæmorrhage. In the latter such symptoms are merely associated, and are not due to the cause of the hæmorrhage, except in the rare cases in which there is an aneurysm of one of the larger intracranial arteries. Most important is the indication afforded by the state of the heart; evidence of its hypertrophy is seldom absent in cerebral hæmorrhage, while it is feeble and often irregular in the softening from atheroma, and presents evidence of valvular disease in embolism. The pulse is tense and often full in hæmorrhage, and in thrombosis from atheroma it is small, feeble, and often irregular, like the action of the heart. In either state evidence of degenerative valvular disease may co-exist. Improvement occurs earlier than in cerebral hæmorrhage. The temperature rises soon after the attack, but falls in a day or two, to rise again slightly during the stage of secondary inflammation. There is more marked mental change than in hæmorrhage, shown at first in excitement, subsequently by depression and deterioration of power. In the cases in which the onset is sudden and the apoplexy profound, a diagnosis from hæmorrhage can only be made by the state of the heart and circulation. In embolism the onset of the attack is commonly sudden, without preceding symptoms, since the state of the brain is normal until the artery is suddenly obstructed. The loss of consciousness is less profound than in hæmorrhage, and is often absent. This is true also of softening from syphilitic disease, in which there are often premonitory symptoms, especially headache. This once proved an accurate indication in a case in which coincident valvular disease suggested embolism. The diagnosis is often also aided by a history of the causal malady. Too much weight must not be laid on the absence of such a history or on the absence of a history of constitutional symptoms, while neither the thoroughness of former treatment, nor a considerable period of freedom from symptoms, has any value whatever as a contra-indication. But with the lapse of time, it does become unlikely that softening is due to this cause; still, it is only after twenty years, and in the absence of any suspicion of a second infection, that the improbability has considerable weight. Optic neuritis, developing after the lesion, occurs in rare cases of softening from embolism, and is practically absent in hæmorrhage (except as a result of Bright's disease). In capillary embolism, if extensive, a distinction from hæmorrhage often cannot be made: the loss of consciousness is profound and lasting. Bilateral softening, such as sometimes results from disease of both middle cerebral arteries, may also (as already mentioned) cause symptoms indistinguishable from those of ventricular hæmorrhage because the second side is usually affected after the first.

The distinction of softening from other cerebral diseases is described in the articles on these.

PROGNOSIS.—The immediate and ultimate pro-

gnosis in an attack of softening of the brain depends on the degree and extent of the symptoms as indicating the extent of the lesion; and on their character, as indicating the region of the brain damaged. Both the near and the remote prognosis is much graver in damage to the medulla and pons Varolii than when the corpus striatum or cerebral hemispheres are affected. Locality is of special importance in regard to the prognosis in softening, because it is by far the most frequent lesion of the medulla or pons that is survived. The intensity of the coma in softening indicates a greater degree of gravity than does the duration of slighter impairment of consciousness. When actual softening has occurred, the damaged tissue never regains its functional power. The congested periphery may recover in proportion to the integrity of the tissues, and to the freedom of the vessels from disease. The prognosis of the residual symptoms corresponds to that of those due to hæmorrhage described in the article on that disease. The chances of a recurrence of softening in another situation depend on the extent to which its causal condition is widely spread or can be removed. In thrombosis from atheroma recurrence is almost certain, but is likely to be deferred in proportion as the attack was due to an adequate exciting cause. In embolism recurrence is rare. The prognosis in syphilitic disease of the vessels depends upon the recognition and treatment of the syphilitic influence so far as recurrence is concerned; but the prognosis of developed symptoms is independent of the fact of their syphilitic cause, or of any treatment to which the patient may be subjected. Treatment can only influence the disease of the wall of the vessel, and this can have no effect in restoring the circulation, since the vessel beyond is closed by clot, or in restoring the structure of the destroyed tissue of the brain. As a matter of fact the course of hemiplegia due to this cause is precisely the same as that of hemiplegia due to softening produced by any other vascular mechanism such as embolism; improvement or recovery is determined by the position of the lesion, and the extent to which the symptoms are not due to the actual destructive softening, and to which they can be compensated. Improvement or persistence of symptoms may coincide with treatment, but the one is not due to it, nor the other the result of its absence.

TREATMENT.—The treatment at the onset of cerebral softening is of great importance, because, although nothing can probably be done to lessen the mischief that has occurred, much may be done to prevent its extension or increase. The closure of a vessel by clot is the great fact of what may be termed the therapeutic pathology of these cases, and the measures to obviate the increase in this process have much in common in the various forms of softening. The variations rendered necessary by the differences in mechanism are considered in the articles on the several vascular diseases. During the acute stage the patient must be kept at perfect rest, with the head moderately raised, flexion of the neck being avoided. During the initial stage of shock, warmth by hot-water bottles, &c., should be applied to the extremities, to equalise the circulation. The bowels, if confined, should be made to act gently; but, unless the evidence of encephalic congestion be early and conspicuous, strong purgation should be avoided. The determination of blood from the brain to the

intestines, involved in purgation, and desirable in cerebral hæmorrhage, is to be carefully avoided in cerebral softening. It is important also to maintain the circulation steady and uniform, avoiding alike undue quickening or slowing of the blood-current. Hence digitalis or strophanthus is useful in moderate doses when there is cardiac weakness or irregularity. In all senile cases, or if there is a gouty diathesis, nitrous ether or other diuretic drug is useful, and, in the latter case, some lithia may be added. Thus the tendency of the blood to clot is lessened, and the risk of the extension of the lesion—always a danger in the early stage of the affection—is lessened or obviated. Stimulants must be given or withheld according to the state of the heart and circulation; when there is doubt whether they should be given or not, it is better to give a small quantity in softening, and to withhold them in hæmorrhage or if the diagnosis from hæmorrhage is doubtful. After the stage of depression has passed, the irritation due to secondary inflammation, indicated by headache and elevation of temperature, needs quietude, laxatives, and sometimes cold to the head. When convulsions are an early and recurrent symptom, mustard plasters to the neck and extremities, and bromide of potassium internally, are sometimes effective; in the early period, ice to the head may arrest them. The fits that attend the actual onset are seldom influenced by treatment; they cease because the tissue is destroyed that is essential for their occurrence. When these fail, hyoscine hydrobromate may be given cautiously, and in small doses ($\frac{1}{300}$ gr.). In embolism the treatment of the cardiac condition is of chief importance. In syphilitic disease iodide of potassium should be given promptly but in doses not exceeding fifteen grains, since a larger amount, from its tendency to cause clotting, may lead to an extension of the thrombus. Although it cannot influence developed symptoms, it is necessary because we do not know what other arteries may be diseased and how near the patient may be to a serious increase in the symptoms.

After the attack has passed, recovery must be aided by maintaining the general health in the best possible condition. The secretions should be kept free, the digestive organs in good order, the habits strictly regulated, and nerve tonics—cod-liver oil, hypophosphite of sodium, strychnine, quinine, and iron—may be given with advantage. The symptoms of chronic softening, whether occurring after an acute attack or coming on gradually, should be treated in a similar manner.

W. R. GOWERS.

BRAIN, Syphilis of the.—SYNON.: Ger. *Gehirn-syphilis*; Fr. *Syphilis cérébrale*.—Syphilis is one of the most important factors in the production of organic brain-disease. The virus appears to act in two ways: (1) Directly upon the blood-vessels and connective tissues generally, with secondary destructive changes in the nervous tissue—a true specific inflammation; (2) by direct influence upon the vitality of the neurones themselves, producing systemic degenerative changes, of which tabes dorsalis and general paralysis are by far the most common and important; these diseases are frequently spoken of as 'parasyphilitic' or 'metasyphilitic' affections.

ÆTIOLOGY.—It was generally accepted, and is still held by many authorities, that syphilitic brain-

disease occurs especially in the later (tertiary) periods. One of the first observers to doubt this view was Rumpf, and he was followed by Bruns, who collected 100 cases, in nearly half of which brain-symptoms occurred in the first year after infection. Naunym, from an analysis of 45 of his own cases and 290 collected cases, came to the conclusion that syphilitic disease of the nervous system appears most frequently during the first year after infection, and that its frequency diminishes from year to year. In the experience of the present writer, out of 40 cases in which the date of infection and the time which had elapsed before the onset of the cerebral symptoms could be determined, four occurred in the first year, seven in the second year, six in the third year, three in the fourth year, and the remainder at subsequent periods. Lang has pointed out that often during the outbreak of the syphilitic exanthem, headache, giddiness, pyrexia, increased frequency or slowness of the pulse-rate, and inequality of the pupils may occur; and he considers these symptoms are probably due to meningeal irritation. The question whether mild or severe forms of syphilitic infection are more liable to be followed by disease of the nervous system is one of importance. Broadbent was one of the first to point out that severe nervous symptoms often follow mild attacks. The writer's experience seems to show that all forms of syphilis may be followed by severe nervous symptoms, and that the mild forms are prone to be followed by serious disease because they are often inadequately treated. It seems, however, a fact that mild forms of syphilis are especially liable to be followed by the parasyphilitic affections; and this fact finds an analogy in the occurrence of diphtheritic paralysis. Most of the leading authorities are of opinion that brain-syphilis is much less likely to follow when the disease has been efficiently treated. Hjellmann has made accurate observations upon this subject, and he has found that 82-85 per cent. of the cases of brain-syphilis were those in which only an imperfect treatment had been carried out.

Traumatism.—Injuries to the head have long been recognised as a cause of syphilitic brain-disease; and frequently a history of a blow or an injury to the head precedes the symptoms of a localised gummatous meningitis of the convexity. Of all the causes which predispose to syphilitic brain-disease, chronic alcoholism is the most important, but all conditions which tend to produce cerebral congestion, excitation, or stress may be contributory factors in the production of the disease, e.g. sun-stroke, excesses '*in Baccho et Venere*,' lead-poisoning, &c.

Sex and age.—The disease affects particularly males between the years of twenty and forty-five, because syphilis is more common in men, and because during this period of life infection is more likely to take place.

Heredity.—Families in whom there has been no trace of syphilis are probably more prone to severe sequelæ, owing to lack of immunity. Hereditary predisposition seems to play a part. As an instance of this, the writer had under his care two brothers who at nearly the same period after infection developed almost identical symptoms of a cerebral gumma. Both were treated with anti-syphilitic remedies and made good recoveries.

Seeing that syphilis is more common in cities

and large towns, this form of brain-disease is more frequently met with in urban than rural populations, but there is not the same disparity in numbers as in general paralysis of the insane.

It is usual to consider syphilitic brain-disease under the following headings:—basic meningitis, meningitis of the convexity, cerebro-spinal meningitis, arteritis, encephalitis, and neoplastic formations or gummata. All these conditions are frequently combined in the severe and early forms of the disease.

1. Basic Syphilitic Meningitis.—SYMPTOMS. *Headache* is one of the commonest, earliest, and most constant symptoms; occasionally it precedes all other phenomena by months and even years. It is not infrequently associated with *vomiting* of a cerebral character; this last symptom may, however, be absent through the whole course of the disease. The pain is paroxysmal, and when it reaches its greatest intensity, it may be boring and excruciating, but this may gradually die down, leaving a dull aching. It is curious but very characteristic that the pain should be most severe at night or in the early morning; it may even awake the patient at a regular time. In the basic form of the disease, the pain is referred to the frontal, temporal, and parietal regions, is deep-seated, and cannot be definitely localised; it may later on spread to the occipital region, the neck, and the spine. Sometimes pain is referred to the back of the eye; in this form of the disease the pain is not usually influenced by pressure, and there is no definite local tenderness as when the convexity is affected.

Stiffness of the neck may be complained of, and there is sometimes retraction of the head and neck. The patient is subject to attacks of vertigo, reeling, staggering, and loss of balance.

Temperature.—It is generally recognised that syphilitic meningitis differs from other forms of meningitis, e.g. tubercular, by the absence of pyrexia, the temperature being usually normal or sub-normal.

Ocular affections.—Of all the symptoms of syphilitic basic meningitis, affections of the optic chiasma and of the nerves supplying the muscles of the eyeball are most frequent and important. Uthoff concludes from his observations that in only about 15 per cent. of all cases of cerebral syphilis are ocular disturbances of some form or other absent. Unilateral paralysis of the oculo-motor nerve, which may be partial or complete, is so common that both Ricord and Fournier designate this ophthalmoplegia '*la signature de la vérole*.' The sixth and fourth nerves are very much less frequently affected than the third. Brain-syphilis may be accompanied by the following ophthalmoscopic changes: (1) choked disc, due to intracranial pressure; (2) optic neuritis; (3) neuritic atrophy; (4) simple atrophic degeneration. Generally speaking, there is a considerable difference in the intensity of the affection of the two eyes. Optic neuritis, as a sole and uncomplicated manifestation of basal syphilis, is extremely rare. The optic neuritis, according to Gowers, is not due to syphilitic disease of the retinal arteries; and in three cases, examined by the writer, in which there was universal endarteritis cerebri, there were no changes in the retinal arteries.

The pupil is more or less dilated, the reflex movement of the iris sluggish or absent both to light and accommodation, and the 'syndrome of Weber' is not infrequently met with, viz. paralysis of the

motor oculi on one side with hemiplegia or hemiparesis of the opposite side. Oppenheim speaks of hemianopsia as being frequent, due either to affection of the optic tract of one side, or to a destructive lesion of one occipital lobe. As a result of the meningitis, other cranial nerves may be affected, but the lesion is usually unilateral. When the fifth nerve is affected, the patient may complain of severe pains over the distribution of the nerve, with hyperæsthesia if an irritative lesion exist; sometimes hypæsthesia or even complete anæsthesia may be found in cases presenting a paralytic lesion. The corneal reflex may be absent; conjunctivitis or even suppurative keratitis may occur; and loss of taste and loss of smell may be found on the same side, due to affection of the mucous membrane of the nose. A lesion of the facial nerve is almost as frequent as of the fifth, and is often associated with deafness, due to the adjacent auditory nerve being involved. Symptoms of affection of the vagus nerve relate mainly to the circulation and respiration; and especially characteristic is a rapid change of the pulse, which may be quick, slow, or irregular; various respiratory disturbances towards the end of life are referred to affections of this nerve. The writer has seen several cases of affection of the spinal accessory nerve causing paralysis of the soft palate and larynx. Unilateral atrophy of the tongue may arise from a destructive lesion of the hypoglossal nerve. It is, however, an astonishing fact that with extensive gummatous meningitis affecting the whole base of the brain, only one cranial nerve, usually the fifth, may be partially paralysed, and yet microscopical examination may reveal extensive infiltration of other nerves by inflammatory material.

Basic meningitis frequently gives rise to polydipsia, polyuria, and sometimes glycosuria. There is usually constipation. There may be paresis in the limbs, but as a rule, unless there be blocking of an artery, there is not paralysis. The spinal membranes are usually affected, but not enough to give rise to symptoms; in five cases, however, the writer found extensive spinal as well as cerebral meningitis, and in several of these, spinal irritative phenomena presented themselves during life in the form of opisthotonus and tetaniform spasms.

Psychical symptoms arise in brain-syphilis when there is general affection of the arteries associated with a gummatous meningitis. In the cases examined by the writer the mental symptoms shown were very probably due to circulatory disturbances caused by an obliterative arteritis, evidence of which was invariably present *post mortem*, as well as to the meningitic process. Heubner showed that when two large branches entering into the formation of the circle of Willis are profoundly affected by obliterative arteritis, mental symptoms arise.

Disturbances of consciousness are usually present and indicate severe and multiple lesions. One of the commonest symptoms is somnolence and a kind of drunken stupor from which the patient is with difficulty aroused. Associated sometimes with this condition is a purposeless motile activity and restlessness. Such patients may or may not respond to questions; they usually have loss of control over the sphincters. The stupor may deepen, or the patient may recover consciousness and hope of recovery be aroused, when quite unexpectedly the drowsy stupor will recur, perhaps deepening into coma, and the patient dies without regaining con-

sciousness. Recurrent attacks of drowsiness, stupor, and coma always suggest the existence of basic syphilitic brain-disease. In the drowsy condition, the tonus of the muscles remains and the reflexes are present, but as the coma deepens both become lost. In all cases of severe brain-syphilis dementia of varying degree is a constant symptom, and all stages between slight impairment of intelligence and gross dementia may be met with: this variability of the dementia is especially characteristic of the disease. Delirium with acute maniacal excitement may be the first indication of mental symptoms; or loss of temper, moroseness, and excitement may usher in the condition. It is not uncommon for a person suffering from syphilitic dementia to be found wandering at large, and be taken up by the police. A frequent condition is mental depression with delusions of persecution and attempt at suicide, and such patients may be dangerous to themselves and others. Mental excitement may alternate with mental depression, and such disturbances may further alternate with comatose attacks and with periods in which consciousness is only partially disturbed and the intelligence is fairly good. Epileptiform fits are not uncommon, and partial or unilateral clonic spasm may occur with consciousness slightly or not at all disturbed. As a rule the fits are transitory and not persistent; they are due to affections of vessels or to gummata or softening in or near the motor area. Tetaniform spasms with opisthotonus occasionally occur in the severe forms of cerebro-spinal meningitis, and, according to Wunderlich, a cataleptic state may be seen.

Should patients recover—and many do partially recover under suitable treatment—they are left mentally enfeebled. There is lack of expression; the speech is slow, often thick and slurred—bradyaphasia, or dysarthria, but seldom complete motor aphasia. There is weakness of memory, slowness of thought and action, loss of will power, often a stolid indifference with a tendency to causeless outbursts of passion or laughter. The patient is emotional, easily moved to tears or mirth, showing a loss of the higher controlling functions of the mind. Sometimes there is a permanent paralysis of the ocular or some other cranial nerve, blindness or deafness, monoplegia, hemiparesis, hemiplegia, dysarthria, or general paresis.

2. Syphilitic disease of the Convexity of the Brain.—A hard and fast line cannot be drawn between disease of the base and of the convexity. Of 24 *post-mortem* examinations of syphilitic brain-disease made by the writer, the majority showed either multiple lesions or diffuse gummatous meningitis.

The process may start in the base or meninges, and remain *circumscribed*, forming a gummatous tumour, or become *diffused* as in meningo-encephalitis. Specific inflammation of the membranes causes extremely severe pains, paroxysmal in character, and besides general headache, there is usually a well-defined localised tenderness on pressure or percussion, which may be independent of spontaneous headache. The general symptoms of meningitis of the convexity may be vomiting, stupor, giddiness, and psychological disturbance. If, however, the lesion be situated over 'a silent part' of the brain, headache may for a long time be the only symptom. Optic neuritis is uncommon; it may even be absent when nearly a whole hemisphere is affected. Gummatous growths like tumours

produce localising symptoms when situated over portions of the brain having specific functions, e.g. the motor area (*vide* fig. 1. BRAIN, Tumours of).

3. Primary Syphilitic Arteritis.—Even without any meningeal affection, one of the earliest and most important symptoms present may be headache (usually more severe than that of arteriosclerosis), giddiness and drowsiness, and various psychical disturbances not unlike some of those of general paralysis. Heubner asserts that headache, giddiness, sleeplessness, irritability, and weakness of memory often precede an apoplectic seizure. These symptoms, together with a transitory monoplegia, hemiplegia, hemiparesis, hemianopsia, hemianæsthesia, word-blindness, and deafness, but especially aphasia, lasting a few minutes, hours, or days, and indicating a temporary circulatory disturbance, are among the most important early indications of endarteritis syphilitica. As long as the lumen of the affected arteries is not obliterated by a spreading thrombosis, a collateral circulation can re-establish the blood-supply to the parts before actual death of tissue occurs. As the endarteritis advances this restoration of blood-supply becomes more and more difficult, and the tendency to stasis and the formation of a thrombus increases, until sooner or later (if active treatment be not adopted) a permanent loss of function occurs. Paralysis may gradually affect the leg, arms, and face; or a hemiplegia may come on quickly, or even suddenly, following an apoplectic fit. Sometimes the loss of consciousness deepens to coma, and the patient dies: usually he regains consciousness, and a partial recovery from the ensuing paralysis occurs; but in the course of weeks, months, or years the paralysis may return or affect the other side of the body, and a pseudo-bulbar or cerebro-bulbar paralysis results. In severe cases of multiple syphilitic arteritis with thrombosis, death usually follows; or should the patient recover, he is generally demented and paralysed.

4. Multiple Gummata.—A patient suffering with this severe form of brain-syphilis is demented, frequently maniacal or stuporose; there may be slurred speech with tremors of the face-muscles; the pupils are unequal and sluggish in reaction to light and accommodation, or do not react at all. He does not respond to the calls of nature. Such cases closely resemble general paralysis, inasmuch as there is always progressive dementia and paresis; there is usually, however, some evidence of a coarse lesion such as a monoplegia or hemiplegia, or strabismus with diplopia, ptosis, and optic neuritis. It is, however, remarkable that in multiple gummata optic neuritis may for a long time be absent. It has been the writer's experience to find multiple gummata always associated with general endarteritis, periarteritis, and basic meningitis. This severe form of brain-syphilis occurs most often in the first few years after the primary infection, and therefore is met with usually in young adults; as a rule it is intractable to remedies, either ending fatally or leaving the patient mentally deficient.

5. Cerebro-spinal Meningitis.—In nearly all the cases of basic meningitis which the writer has examined, he has found evidence, both gross and microscopic, of some involvement of the spinal membranes. As a rule, the brain-symptoms are so predominant that the spinal symptoms are overlooked: three out of seven cases, however, exhibited symptoms during life—namely stiffness in

the neck, pains in the back, radiating pains and girdle-sensation, with hyperæsthesia or anæsthesia over the buttocks, trunk, or extremities, indicative of irritation or destruction of the posterior roots. There may in severe cases be tetaniform spasm and opisthotonus, followed by atrophic paralysis indicating affection of the anterior roots. These symptoms, pointing to affection of the spinal membranes, naturally add to the gravity of cases of basic meningitis. Finally it must be remembered that syphilitic brain-disease in all its forms may now and then be accompanied, preceded, or followed by tabes dorsalis or general paralysis.

PATHOLOGY.—*Naked-eye appearances of Brain-Syphilis.*—Essentially the changes are the same in all cases; the process is one of inflammation which has nothing absolutely 'specific' about it, but which exhibits certain features characteristic of syphilis. There is considerable resemblance between tubercular and syphilitic brain-disease, and it is often extremely difficult to distinguish one from the other by the naked-eye appearances.

Syphilitic new-growths belong to the 'granulation tumours' of Virchow, or the 'infective granulomata' of Klebs; they are termed gummata. The gummatous process, which nearly always starts in the membranes, may extend over the surface of the brain in the form of an exudative meningitis or along the vessels into the substance of the brain, causing a definite localised tumour. If the process starts anywhere about the base, as in the interpeduncular space and optic chiasma, it usually spreads into the Sylvian fissures, and over the whole base of the brain, covering the vessels and cranial nerves with a gummy exudation which has a semi-solid consistency not unlike agar or gelatine culture-media in appearance. The membranous deposit may be removed with the finger when of comparatively recent origin; when of some standing it is drier and firmer; it may be grey or grey and red in colour, or semi-translucent, yellowish or speckled. Under treatment, this inflammatory exudation can, in great measure, be absorbed. The vessels appear thickened and of a dirty white colour like wet wash-leather; laid on the finger they can easily be cut transversely, and the lumen may be seen partially or completely occluded; the endarterium is markedly thickened, usually more on one side than on the other, giving the section a 'half-moon' appearance. The vessels may feel stiff like cartilage, but this degree of resistance is not met with in acute cases. Besides the nodular and general endarteritis, there is always a similar periarteritis. Small nodules, visible to the naked eye, lie scattered about the base of the brain. In some cases these miliary gummata upon microscopical examination seem to consist of small vessels affected with endarteritis and nodular periarteritis; they somewhat resemble miliary tubercles.

Localised new-growths (gummata).—These may be single or multiple, and vary in size from a pea to a pigeon's egg. When single and circumscribed they usually start from the meninges of the base of the brain or hemispheres, causing adhesive inflammation; but when multiple, they may be scattered about in various positions, such as the hemispheres, pons, crura cerebri, the base of the brain, the basal ganglia, and even the lateral ventricles; they do not occur in the cerebellum. Gummata vary much both in consistency and

colour, as well as in general appearance; their consistency is usually unequal in different parts, the younger peripheral growing tissue being soft, succulent, and vascular, the older dry, firm, and non-vascular. Hence the edges appear grey, greyish-red, or red, while the central portions are yellowish, owing to the occurrence of necrotic changes akin to caseation. The caseous mass does not usually form a well-defined nodule, but is more often broken up into irregular areas which coalesce here and there by grey fibrous strands, or soft greyish-red granulation-tissue. There is little tendency to calcification or to the formation of an abscess.

Microscopical appearances.—The neoplastic formation, whether circumscribed or diffuse, is essentially the same. It consists of an inflammatory exudative product containing enormous numbers of round cells, indistinguishable from migrated leucocytes, in a coagulated serous fluid. This forms the main constituent of the membranous deposit formed at the base of the brain; it invades all the adjacent structures, the membranes, the walls of the vessels, the pial septa, and the roots of the cranial and spinal nerves. The acute inflammatory process causes congestive stasis in the vessels, so that, wherever this inflammatory process has extended, venous and capillary stasis occurs, independently of and apart from the organic changes in the walls of the vessels. Besides this, there is active proliferation of the mesoblastic connective tissue-elements in the form of abundant spindle-shaped and stellate cells. In the older parts of the gummatous process these formed elements may alone remain, the inflammatory products having been absorbed. The changes around the vessels are essentially of the same nature, namely, infiltration of the walls of the vessels with inflammatory products, causing a periarteritis, which may assume the form of a nodule (*periarteritis nodosa*). In the older parts of a gumma, the recognition of the existence of a vessel is only possible by the crinkled line of the still undestroyed elastic lamina.

Syphilitic endarteritis is characterised microscopically by a cellular proliferation of the endarterium; it frequently gives rise to the appearance of little nodules on the arteries, owing to the process affecting one side of the vessel especially, but it may affect the whole of the circumference. It is one of the most frequent results of syphilis, and may be associated with meningitis. It affects especially the vessels of the circle of Willis, the arteries of the Sylvian fossa, and the lenticulo-striate vessels. It may or may not be associated with periarteritis, which is usually present where there is meningitis. The endarteritis is the result of irritation and thickening of the endarterium, and is brought about by proliferation of the subendothelial connective-tissue cells; the inflammatory exudation and round-celled infiltration distends the spaces between these proliferated cells. According to Heubner, the characteristic feature of endarteritis syphilitica is that it never undergoes caseation, and therefore never becomes atheroma. This dictum is, generally speaking, true, but there are many reasons for believing that it is too exclusive.

Congenital syphilitic brain-disease.—According to Barlow and Bury, the most common brain-lesion met with in hereditary syphilis is a cortical sclerosis, which microscopically examined shows atrophy of cells and overgrowth of neuroglia-tissue.

The condition may arise (a) as a result of specific endarteritis; (b) secondary to a chronic meningitis; or (c) it may be primary and apart from meningitis or arteritis. The symptoms, as in the acquired form, may be mental or physical. The mental condition may indicate arrested development (idiocy and imbecility) or premature decay (dementia). These authors state that the clinical type of intracranial hereditary syphilis is a spastic paresis of the limbs associated with dementia or amentia, the patient being very frequently the subject of epileptiform convulsions.

DIAGNOSIS.—The early diagnosis of syphilitic brain-disease is of great importance on account of its curability, provided the disease is treated before destructive tissue-changes have occurred. Such changes, however, in the 'silent parts' of the brain may proceed to an advanced degree without producing well-defined symptoms. Thus the diagnosis of syphilitic brain-disease which is producing only mental symptoms is attended with far greater difficulty than when there co-exists some definite objective symptom, such as paralysis of a cranial nerve. It has already been pointed out how frequently ptosis and other evidences of paralysis of the third nerve occur in brain-syphilis, and it is noteworthy that cerebral syphilis seldom strikes without warning symptoms. Even in the absence of any paralysis, or evidence of syphilis, and in spite of persistent denial of infection, if a young or middle-aged person suffers with mental symptoms accompanied by headache, especially nocturnal headache, or if there is a history of a fit followed by transitory aphasia, paralysis, or paresis, it is justifiable to suspect brain-syphilis, although the symptoms might point equally to general paralysis. Frequently the correctness of such a diagnosis is confirmed by rapid improvement under energetic anti-syphilitic treatment.

In women far greater difficulties arise in diagnosis: the primary sore and secondary symptoms are often overlooked, and there are frequently no residua on the body; but 'parchment' scars, enlarged cervical glands, evidence of old iritis, and especially a collar of pigmentation around the neck should be looked for, in the absence of more obvious syphilitic manifestations. A very important matter is the history of miscarriages, abortions, dead fetuses, and premature births. According to Birsch-Hirschfeld, syphilis is responsible for two-thirds of such cases. It is, however, equally important to remember that syphilitic parents may have perfectly healthy children.

Seeing that syphilis may attack any part of the cerebro-spinal nervous system, causing general or local irritation or destruction, the complex of symptoms arising therefrom may simulate almost any disease of the nervous system. Such diseases are—new growths, including tuberculosis; tubercular meningitis; disseminated sclerosis; arterio-sclerosis; epilepsy; hysteria; neurasthenia; alcoholism; uræmia; lead-poisoning; tabes dorsalis; general paralysis of the insane; mania; melancholia; epilepsy with dementia; dementia; and local or diffuse softening, the result of embolism or thrombosis.

It is of such importance to the practitioner to be able to differentiate these diseases from brain-syphilis that some of the more important diagnostic points may here be indicated; but for further information reference may be made to the special articles upon each of these subjects.

New growths (including tubercle) seldom show the same spontaneous remissions and exacerbations as gummatous syphilitic meningitis. Symptoms of intracranial pressure, e.g. optic neuritis and vomiting, are usually much more severe in cases of new growths. The headache is continuous, and as a rule does not tend to be nocturnal to the same extent as in syphilis.

Tubercular meningitis, although common in young children, is relatively rare in adults; it is acute and progressive, and there are usually signs of tubercular disease in the lungs; there are, as a rule, more stiffness and retraction of the neck, and more muscular rigidity than in brain-syphilis. The irritative phenomena precede the paralytic, and the pyrexia is more definite and continuous than in syphilitic meningitis. Syphilis and tuberculosis may be combined, and then syphilitic remedies prove useless.

Multiple disseminated sclerosis.—Seeing that syphilitic disease of the arteries may produce multiple foci of softening, a differential diagnosis is extremely difficult and sometimes impossible. The true insular sclerosis usually affects young women rather than men. It may commence with an ocular paralysis, but it is much more often the sixth nerve than the third which is affected; and whereas nystagmus is rare in syphilis, it occurs in 60 per cent. of the cases of disseminated sclerosis.

Pupil-symptoms are common in syphilis; likewise aphasia and alexia and cortical epilepsy; the scanning speech characteristic of disseminated sclerosis should be differentiated from the dysarthria and bradyphasia of syphilis. Visual affections are common in both diseases, but complete optic atrophy and hemianopsia are not met with in disseminated sclerosis. Finally, it should be borne in mind that whereas syphilis attacks the membranes first and the cortical and spinal substance later, insular sclerosis commences in the white matter of the cerebro-spinal axis, and therefore meningeal and nerve-root symptoms point to syphilis.

Arterio-sclerosis.—Many cases of this are of syphilitic origin, but the arterio-sclerosis of people past middle life is a degenerative process, and when it affects the cerebral arteries, it is attended by various psychical disturbances, arising from disorder of the cerebral circulation, such as fainting fits, vertigo, mental depression, and headache. As a rule, however, the headache is much less severe than in syphilitic endarteritis.

Partial, unilateral, or universal convulsions may occur in *epilepsy*, *lead-poisoning*, *uræmia*, *general paralysis*, and *alcoholism*, as well as in cerebral syphilis. In such cases very difficult problems often present themselves. In cases complicated by alcoholic excess, it is well to wait until the effects of the alcohol have passed off. Epileptiform convulsions due to brain-syphilis are frequently Jacksonian in type and caused by syphilitic meningitis, and are therefore accompanied by severe headache and tenderness on percussion and pressure in an area of the skull corresponding to a portion of the motor area which presides over the group of muscles in which the fit starts.

Early cases of *Tabes dorsalis* with ocular paralyses may be mistaken for syphilitic meningitis. Ophthalmoplegia interna points rather to tabes or dementia paralytica than to brain-syphilis. The parasymphilitic affections are as a rule comparatively

painless. It must, however, be borne in mind that some cases of true brain-syphilis may be accompanied or followed by the progressive primary degenerative process. It is well to remember that just as brain-syphilis may simulate almost any form of organic brain-disease, so it may occasion or simulate almost any form of mental disease.

PROGNOSIS.—Naunyn states that out of 88 cases of cerebral syphilis 24 recovered, and 49 improved under treatment; 5 died and 10 showed no improvement. The writer's experience agrees closely with this; foreign observers give a less favourable percentage. All the writers on this subject are agreed as to the beneficial influence of early treatment. It appears to be the case that nervous affections are more likely to occur when mercurial treatment has either been insufficient or not practised. The most favourable cases are those which point to a localised gummatous process; the most unfavourable are those which simulate general paralysis, thus showing signs of universal affection of the brain: cases which indicate multiple softening from arterial occlusion are also very grave. Probably endarteritis is the most dangerous because it is the most insidious of all forms of cerebral syphilis; the warning symptoms are apt to be neglected, and if the transitory paralyses which have been alluded to are not followed by treatment, permanent loss of function ensues, for anti-syphilitic treatment, however vigorous, cannot replace nerve-tissue once destroyed. Pure basic meningitis does not indicate a bad prognosis, neither does involvement of a cranial nerve, e.g. the motor oculi—rather the reverse, for it brings the patient early under treatment. Marked optic neuritis may disappear, and restoration of sight may be complete under treatment, whereas progressive neuritic atrophy generally ends in blindness. Basic meningitis is much more favourable when limited to one side and when there is reason to suppose that it is not associated with extensive arteritis; basic endarteritis is liable to cause softening in the pons or medulla, leading to serious paralyses and fatal complications. The prognosis of brain-syphilis largely depends upon the age, habits, life, and occupation of the individual. All causes which tend to lower the general vitality of the tissues of the body or throw stress upon the nervous system influence unfavourably the prognosis, especially sexual and alcoholic excess. Age is a relative thing; the more worn out a man's tissues are, the more active usually is the syphilitic poison, and it attacks the *locus minoris resistentiæ*.

TREATMENT.—*Prophylactic.*—All causes which tend to lower the general vitality of the body or which produce nervous excitement or depression should be avoided by a patient suffering with symptoms of secondary syphilis.

Therapeutic.—As a rule the writer has found the most benefit to result from mercury combined with iodide of potassium; some authorities prefer only the latter in doses of 10 to 30 grains three times a day; but it is better to combine with it mercurial inunction, or even mercurial injection, when it is necessary to get patients rapidly under the influence of anti-syphilitic remedies. If the patient can afford it, a systematic inunction-course at Aix is advisable in many cases. If there is local pain, as in meningitis of the convexity, the head may be shaved and mercurial ointment, combined with lanoline, rubbed in over the painful part as well as into the body. Should the patient, owing to vomiting, be unable to

retain medicine and food, iodide may be given in the nutrient enemata. For out-patient practice, or for people who are not under constant supervision, or for whom it is impossible to adopt treatment by inunction, a combination of the liquor hydrargyri perchloridi (1 to 2 drms.), with 20 to 30 grains of iodide, and tincture of cinchona is of great use. Care should be taken to tell the patient to clean the gums and teeth after each meal, and a mouth-wash of chlorate of potassium may be ordered. Many patients' gums are 'touched' long before they have had efficient mercurial treatment, owing to neglect of these precautions. As a rule good effects will begin to show themselves in the first week or two, but the treatment should be continued for months; for if at first it does not lead to visible improvement, it may prevent the extension of the disease. It is well to keep patients for months and even years on moderate doses of iodide occasionally combined with mercury, according to whether it is an early or late case after infection. It is a most important element in the treatment to point out to the patient the desirability of leading a sober and steady life, and also it is the duty of the medical man to cheer up the patient, thereby promoting digestion, nutrition, and sleep, and counteracting the tendency to syphilophobia and hypochondriasis.

FREDERICK W. MOTT.

BRAIN, Tuberculosis of.—See BRAIN, Tumours of; and MENINGITIS, Tubercular.

BRAIN, Tumours of.—**SYNON.** : Fr. *Tumeurs cérébrales*; Ger. *Gehirngeschwülste*.

DEFINITION.—Under the term 'cerebral tumours' it is convenient to include not only tumours in the strict sense but also all forms of cysts, parasitic or otherwise, and aneurysms, as their clinical phenomena correspond closely with those of tumours. Syphilitic tumours (gummata) are, however, dealt with in a separate article. See BRAIN, Syphilis of the.

PATHOLOGICAL ANATOMY AND HISTOLOGY.—The following varieties of tumour may occur within the cranium: (1) *Gliomata*.—These are usually solitary, and are of a greyish-white, greyish-red, or dark-red colour. Sometimes this form of tumour may have the general appearance and consistence of a local hypertrophy of the normal grey or white matter; it can usually, however, be recognised by difference in colour and consistence from the surrounding normal substance. It may appear shining grey and transparent, sometimes greyish-white or red; or it may have a mottled appearance. The red colour depends upon congested vessels and hæmorrhages; and the vascularity may be so great in some cases as to give rise to the name *angio-glioma*. As the tumour is due to an exuberant proliferation of the normal embryonic connective tissue, it has no defined limits, but passes gradually and insensibly into the surrounding normal structures. Cavities and cysts may form in the tumour, owing to degenerative changes, and these cysts contain sometimes a clear, sometimes a turbid, sanguinolent brownish-black fluid. From the rupture of dilated vessels, hæmorrhages may occur of varying size, causing sudden symptoms during life, resembling an apoplectic seizure; and at the autopsy, the extravasated blood tearing up the brain tissue may be so obtrusive, that the true nature of the disease may be overlooked. Again, it may simulate a focus of softening, owing

to the fatty degenerative changes which have occurred in the growth. The tumour may be of almost any size, from that of a pea to that of the fist, or even larger. All authorities agree that this form of tumour does not spring primarily from the meninges, and it is probable that, as in the spinal cord, it arises in the grey matter. It is relatively frequent, for of 600 collected cases of cerebral tumours 91 were said to be gliomata. This form of tumour is met with most frequently—in order—in the following situations: centrum ovale, cortex cerebri, cerebellum, basal ganglia, pons, and medulla. When occurring in the two last-named situations, it is frequently combined with a similar growth in the spinal cord. Histologically the structure corresponds to the neuroglia, hence its name; the growth consists of delicate cells, with round or oval nuclei surrounded by a smaller amount of protoplasm; and projecting from the cells are numerous branched processes. A felt-work of delicate fibrils, consisting probably for the most part of the cell-processes, is seen in a microscopical section lying between the cells. The fibrillary structure may be so abundant in some tumours as to give them a tough fibrous character, or mucoid changes may lead to a soft tumour, termed a *gliomyxoma*. The tumour usually contains abundance of nerve-elements—fibres and ganglion-cells—in those parts where hæmorrhages or degenerative changes have not taken place, for the growth tends to infiltrate and push aside the nervous elements, without destroying them. Such growths may be looked upon as local malformations of the brain, arising as a result of abnormal embryonic development, although frequently a history of a blow on the head has preceded the manifestation of symptoms.

2. *Sarcomata*.—Sarcomata occur more frequently in the adult than gliomata. According to Allen Starr, of 600 recorded cases of cerebral tumour, 120 belonged to the sarcoma-group, 86 occurring in adults and only 34 in children or young people under twenty. Sarcomata seldom arise in the brain-substance, and very rarely in the cranial nerves. Much more frequently they commence in the fibrous structures of surrounding tissues, e.g. the membranes of the brain, the periosteum of the cranial bones, and the bones themselves, especially those of the base of the skull. All known types of sarcoma may occur (*see* TUMOURS: Sarcoma). Many of these arise as a result of metastatic deposits. Sarcoma arising in the membranes is usually either a round nodular tumour, or a diffuse superficial thickening, with a well-defined border, often pressing the brain-substance before it, and forming as it were a nest. Primary sarcomata are usually solitary and may vary greatly in size. The consistence varies according to the nature and vascularity of the growth. In the hard variety, the cut surface appears fibrous, and of a greyish-white colour; the soft variety may be yellowish, yellowish-red, or greyish-red, according to the amount of degenerative change in the growth, its vascularity, and the presence of hæmorrhages of recent or remote date. Cystic degeneration sometimes occurs, especially in the cerebellum, and rarely calcification or even ossification of a sarcoma may take place. Although primary sarcomata are usually solitary, they may be multiple, and occur simultaneously in the brain, spinal cord, and ganglia.

3. *Endotheliomata*.—According to Ziegler, a

new growth may arise from the endothelial cells of the pia-arachnoid membrane. Examined microscopically such a growth shows a stroma of fibrous tissue in which there are nests of endothelial cells.

4. *Rarer forms of Tumour* are pure fibroma, cystic fibroma, lymphangioma, osteoma, osteofibroma, osteo-sarcoma, enchondroma, exostosis, and psammoma. This last form of tumour only occurs in the meninges, in the pineal gland, and rarely in the choroid plexus. It usually causes no symptoms. When the tumour is cut into, the knife grates, owing to the existence of calcareous concretions. Examined microscopically, these growths are seen to contain round concretions of various sizes consisting of superimposed flattened cells, with a homogeneous appearance, arranged concentrically like an onion. Cholesteatomata, angio-sarcomata, angiomas, dermoid cysts, lipomata, and other growths, e.g. tumours of the hypophysis cerebri, are in rare instances met with.

5. *Carcinomata*.—Carcinoma is nearly always secondary, but sometimes primary. It has been described as primary in the cranial bones, the meninges, and the choroid plexus. It is probable that in some instances a primary growth has been overlooked in some other part of the body, and it is likely that a number of those described as carcinomata were really sarcomata.

6. *Tubercular masses*.—Tubercular 'tumours' occur most frequently in young people. Of 300 tumours which occurred in young people, 152 were tubercular: of 300 occurring in adults only 41 were of this character. The earliest age at which a tubercular tumour has been found *post mortem* was 23 days; the mother of the child was also tuberculous. The tumour was of the size of a hazel-nut (Demme). Statistics disagree as to whether tubercular tumours are more frequently solitary or multiple. According to Starr, only about one-fifth were multiple; according to Gowers, less than one half were solitary. The size may vary from a pea to a chestnut. They are met with most frequently, according to Gowers, in (1) the cerebellum, (2) the cortex, (3) the pons. The naked-eye appearance is usually characteristic. On transverse section they have a more or less sharply defined peripheral zone of a grey or greyish-red colour, with a yellowish cheesy centre, which sometimes, owing to its having undergone softening, contains a turbid, yellowish-white fluid. Microscopically, the peripheral zone appears to consist of a granulation-tissue, consisting of round cells and giant-cells: in the giant-cells tubercle-bacilli can usually be found, whereas they may not be discovered in the central part, which has undergone caseation. Very rarely a tubercular abscess may occur; and it is not very rare on the *post-mortem* table in asylums to find old calcified tubercular tumours in the brains of patients who have suffered with epilepsy and dementia. It is seldom that 'solitary tubercle' of the brain forms the primary seat of infection, tuberculosis being usually met with in other parts of the body. Tubercular tumour is not uncommonly combined with tubercular meningitis, and is not infrequently the cause of an accompanying hydrocephalus.

7. *Syphilomata* (gummata).—*See* BRAIN, Syphilis of the.

8. *Cysts*.—As already mentioned, cysts may be formed in the brain as a result of degenerative processes occurring in tumours, such as glioma,

sarcoma, and carcinoma; but occasionally in England, and not at all uncommonly abroad, parasitic cysts occur in the brain. Of these there are two forms, viz. (1) *Cysticercus cellulosæ*, and (2) *Tænia echinococcus* (see ENTOZOA). The former are not at all uncommon in Germany, for in 5,300 autopsies made at the Berlin Pathological Institute there occurred 87 cases of this parasite, 72 of these being in the brain. Hydatid cysts are not infrequently met with in the brain in those countries where infection by this parasite is common, e.g. Australia.

9. *Aneurysms*.—Apart from the miliary variety intra-cranial aneurysms occur usually on the arteries of the base or their branches before their entrance into the brain-substance. They occur frequently at the point of bifurcation of an artery; they are usually single, but sometimes multiple. Of 156 cases collected by Gowers, the aneurysm was seated in 44 on the middle cerebral artery, in 41 on the basilar, in 23 on the carotid, in 14 on the anterior cerebral, in 8 on the posterior communicating, in 7 on the vertebral, and in 6 on the posterior cerebellar. It will thus be seen that more than half occurred on the two first-named arteries, a fact of some importance in connection with the relation of symptoms to diagnosis, since the neighbouring parts of the brain may be compressed or indented, atrophied or softened. If adjacent to brain-substance, the aneurysm may by pressure form a recess, in which it lies. Sometimes the bones of the skull may be eroded. Frequently one or more cranial nerves may be compressed by the aneurysm, the pressure resulting in their atrophy; and sometimes a nerve may be found adherent to the wall of the aneurysm. It is not uncommon for a cerebral aneurysm to become filled with a laminated clot, which may result in obliteration of the sac and spontaneous cure; but more often the aneurysm suddenly ruptures, causing death from hæmorrhage.

ÆTIOLOGY.—A number of the new growths are due to congenital developmental anomalies. These include the rare dermoid cysts, teratomata, angiomas, and probably gliomata. Very little is known of the causes underlying cerebral tumours, except those of infective or parasitic origin, nor can we explain why in some people these tumours should occur in the brain and not elsewhere. A neuropathic inheritance plays no essential rôle in the development of cerebral tumours, nor does mental stress; but experience seems to point to the fact that blows and injuries of the head are followed by symptoms indicating the existence of an intra-cranial tumour, although it must be remembered that a certain number of cases, in which apparently a tumour followed a blow or injury of the head, may be explained by the effects of a hæmorrhage into a tumour in which the symptoms were previously absent or ill-defined. This is especially liable to occur in the case of gliomatous tumours. Again, sudden onset of fatal symptoms may follow a blow or injury of the head in aneurysm owing to rupture of the sac. Aneurysm usually is associated with degenerated arteries elsewhere. It occurs especially in syphilitic persons; it may, however, result from infective arteritis, the result of plugging of a cerebral artery by an infective embolus in ulcerative endocarditis.

The *pathological effects* of tumours are related to (1) direct irritation or destruction of adjacent

nervous substance, inflammation, and cedema; (2) destruction of the brain-substance or the cranial nerves by pressure and obliteration of the vascular supply. The disturbance and loss of function occasioned by these processes form the principal guides in inferring the situation and to some extent the size and nature of the growth. But a tumour seated within the cranial cavity by the production of increased intra-cranial pressure causes a number of general symptoms, common to all cerebral tumours, consisting of disturbances in the circulation and the production of internal hydrocephalus.

SYMPTOMS.—As a rule general symptoms precede local, and the onset of both may be slow and gradual; sometimes the symptoms have been so ill-defined as to have been overlooked during life, and the condition has only been discovered *post mortem*. Not infrequently localising symptoms may be entirely absent during the whole course of the disease.

A. *General*.—1. *Headache* is one of the earliest, most constant, and most distressing of symptoms, and is seldom absent during the course of the disease. It may be a dull and continuous pain affecting the whole head, and increased by every forced act of expiration, such as coughing or sneezing. It is the most severe and persistent of all forms of cephalalgia, and even when the patient is in a stuporose or semi-conscious condition, he still manifests by his moaning and the holding of his hands to his head the intense pain which the disease is causing. The pain is subject to exacerbations, which usually wake the patient in the early morning, a symptom which is very frequent in syphilitic tumours; it is often diffuse, sometimes deep-seated and not localised to any particular part of the head. It frequently affects the frontal region, but this does not necessarily show that the tumour is in the frontal lobe; on the other hand, a continuous pain over the back of the head and neck rather suggests the posterior fossæ of the skull as the seat of the tumour, especially if the pain radiates down the spine and upper limbs. This *general* pain, which is due to increased intra-cranial pressure, may be associated with very acute, excruciating, burning *local* pains, limited to a precise circumscribed spot, which frequently indicates the involvement of the meninges by the growth, and therefore its exact situation; over this seat there is often marked tenderness on deep pressure or percussion. Pain confined to one side of the head is usually but not invariably indicative of tumour of that side. All conditions which tend to cause hyperæmia of the brain increase the pain, e.g. alcohol, mental excitement, muscular exercise, forced acts of expiration, and, in some cases, even change of position. The pain persists, however, when all exciting influences are removed, and it cannot be completely and continuously averted by narcotics.

2. *Optic neuritis* is the most important symptom of cerebral tumour, as it is only in isolated cases that this symptom has been proved to have been absent during the whole course of the disease. It occurs at some period before death in three-fourths of the cases, and is generally bilateral, but usually one eye is affected more than the other. It may be present without the patient complaining of affection of sight, and the visual acuity may be quite normal; in advanced cases vision is generally affected and there is an irregular diminution of the

visual field and a lowering of the acuity of central vision, which may go on to complete blindness. Transitory amaurosis may occur, due, not to the direct result of the papillitis, but to internal hydrocephalus, which causes distension of the third ventricle and depression of its floor, thus compressing the optic tract. Post-neuritic atrophy may result; as a rule, however, the production of this takes a considerable time; even when there is atrophy, there are usually signs of papillitis present (see OPTIC NERVE, Diseases of). The causes of changes in the fundus, which English authorities speak of as optic neuritis, and German as Stauungspapilla or choked-disc, is a matter of controversy. There are three views: (1) That it is due to the obstruction to the return of venous blood by the ophthalmic vein, the increased intra-cranial pressure causing compression of the cavernous sinus; but this theory of von Graefe has been disproved by the fact that free anastomosis occurs between the ophthalmic and facial veins. (2) That the intra-cranial pressure interferes with the return of lymph from the sheath of the optic nerve into the sub-arachnoid space, causing hydrops of the sheath, which in turn compresses the veins and obstructs the outflow of blood from the papilla. (3) That the condition is due to irritation and inflammation of the sheath of the optic nerve, produced either by the presence of toxic substances in the cerebro-spinal fluid produced by the tumour, or by direct downward extension of a meningitis. According to Gowers a combination of causes may be in operation. No doubt mechanical stasis in the veins would soon be followed by exudation, and then all the appearances of inflammation would be produced. One argument in favour of the mechanical theory (2) for the explanation of this condition is the fact that choked disc or optic neuritis may be greatly benefited or even disappear after trephining has been performed and the cerebro-spinal fluid allowed to drain off. Some of the cases have been noted as improved in the first day after the operation, and in the course of some weeks the neuritis has completely disappeared. The only conclusion at present possible is that intra-cranial pressure is an essential and fundamental, if not the sole, cause of this important symptom. In many cases of tumour an ampullary swelling has been observed where the sheath is weak at the entrance to the eyeball, but it is often absent, even in acute cases, and the writer has seen it well marked in a case of meningeal hæmorrhage, causing great compression of the cerebral substance. Degeneration of the posterior roots and posterior columns of the spinal cord is sometimes observed and is probably also due to the increased pressure of and chemical changes in the cerebro-spinal fluid.

3. *Vomiting*.—Vomiting is a frequent but not constant symptom. It occurs in rather more than one-third of the cases (Jacoby). When present it is an early and most persistent symptom, and then forms a most troublesome feature of the disease. It may occur without the presence of food in the stomach, e.g. on waking in the morning. It is especially liable to come on when the headache is severe; the tongue, however, usually remains clean, and the appetite may not be much affected. It often ushers in or follows an epileptiform attack. Its cause is probably irritation of the vomiting centre in the medulla, brought about by the increased intra-cranial

pressure or by reflex irritation through the meningeal nerves.

4. *Vertigo*.—Vertigo is usually associated with vomiting, but if severe, and especially if it occurs early in the disease, it must be considered as a special rather than a general symptom, pointing to the existence of a tumour in the cerebellum or its peduncles.

5. *Pulse*.—Permanent or temporary slowing of the pulse occurs pretty frequently. It is usually independent of headache, and, when it occurs as an early symptom, points to a tumour of the medulla; but it may arise as a result of increased intra-cranial pressure, for Horsley has found that after relief of the pressure by trephining, the pulse has quickened. Slowing of the pulse may be accompanied by respiratory disturbances.

6. *Fainting Fits and Apoplectic Seizures* may occur, produced by hæmorrhage into the tumour, causing sudden increase of intra-cranial pressure.

7. *Epileptiform Convulsions*.—Epileptic attacks, with loss of consciousness, may arise in every stage of the disease; although usually a late symptom, epilepsy may belong to the earliest phenomena, in fact may precede other symptoms by many years. A certain number of cases of tumour occur, in which fits form a prominent symptom, although the tumour is not seated in the Rolandic area. The writer has seen three cases of internal hydrocephalus, caused by tumours seated in the third ventricle, in which general convulsions formed a prominent symptom, associated with paroxysmal attacks of drowsy stupor and lethargy. Usually, however, epileptiform convulsions indicate affection of the central convolutions, especially when they are Jacksonian in type; but in slowly growing tumours, symptoms like idiopathic epilepsy may ultimately develop. Instead of typical epilepsy, attacks of simple loss of consciousness may occur, with or without automatic and forced movements. Again, the spasms may resemble an hysterical attack, or simple convulsions may occur with retention or only impairment of consciousness. In tumours of the posterior fossæ tetanic contractions of the muscles of the trunk, with retraction of the head, have been observed.

8. *Psychical Symptoms*.—The expression of the patient is often characteristic of a profound mental change. There is a dull, heavy, drowsy or stuporose condition. The patient in conversation does not reply readily, is listless and easily fatigued, lacks attention, and is unable to collect his thoughts. The speech is slow, sometimes slurred and confluent, and the reaction-time in answering questions is much prolonged. The intelligence often suffers, the memory is enfeebled, and sometimes there is great mental depression, and in rare cases mania. Attacks of mad excitation with delusions and hallucinations may occur, and cause the patient to be taken to an asylum; and it is important to remark in this connection that psychical symptoms may form the first evidence of the brain-disease. Indeed tumours of the brain are not uncommon on the *post-mortem* table at asylums (at least 2 per cent.). Later, as the intra-cranial pressure increases, the symptoms become more marked and the existence of disturbances of consciousness is manifested by the drowsy stuporose expression, by the loss of interest to surroundings, and by the passage of urine and fæces in the bed. In the last stages the loss of consciousness becomes more profound and tends to coma.

9. *General Wasting and Bodily Weakness* occurs, due to the vomiting, headache, and insomnia, and to the knowledge too often of an incurable disease. These together produce a marked change in the metabolism of the whole body, which in a measure is increased by auto-intoxication brought about by obstinate constipation.

10. *Polyuria with or without Polydipsia* may occur, especially in syphilitic tumours of the brain. Glycosuria is met with sometimes and indicates, when other symptoms agree, tumour of the medulla.

B. LOCAL SYMPTOMS AND LOCAL DIAGNOSIS.—Although tenderness on pressure and a high-pitched resonant note over a particular portion of the skull may in some cases afford indication of the existence of a tumour beneath, yet the local diagnosis of the lesion depends mainly upon the regional or focal symptoms caused by direct or indirect involvement of structures possessing particular functions (see fig. 1)

Small tumours, and even tumours of considerable size, may exist in certain regions of the cerebral

patient was trephined over this region, but the *post-mortem* examination showed that this was only one of several tumours.

Tumours of the Hemispheres.—*The motor area.*—A tumour situated in the central convolutions of the Rolandic region of the cortex may produce two classes of localising symptoms: (a) irritative; (b) destructive; the former are characterised by cortical epilepsy, the latter by cortical paralysis, generally a monoplegia. Cortical epilepsy is manifested by tonic followed by clonic spasm affecting one limb, or a portion of the limb, or the face, commencing in a group of correlated muscles, which preside over a representative movement, and spreading in a definite way, according to the situation of the tumour. In a great number of cases the muscular spasm is preceded by sensory phenomena, such as a feeling of cramp or numbness, and tingling of the skin of the parts. The march of the fit is of great importance to observe, for it will commence in the same region and spread in the same way, e.g.

FIG. 1.—Left hemisphere, showing the situation of the cortical projection-centres

hemispheres, especially the right, without giving rise to any symptoms other than those due to increased intra-cranial pressure. Again, tumours such as the infiltrating gliomata may be situated in the white substance of the hemisphere, and either give rise to *no* localising symptoms, or by pressure, extension, or hæmorrhage, affect structures with particular localising functions situated in the neighbourhood, or even at some considerable distance. A false notion of the position and size of the tumour may thus arise. For example, a large tumour in the right frontal lobe might extend to the motor area, and the first localising symptom might be Jacksonian epilepsy. Likewise, multiple tumours may exist, but only one of these be situated in a region which would occasion localising symptoms; consequently an erroneous prognosis as to the beneficial result of operative procedure might be arrived at. The writer recently saw a case of multiple tubercular tumours in which the most prominent localising symptoms were cortical epilepsy, starting in the right facial muscles, and partial aphasia. The

it may begin in the face, indicating involvement of the lower portions of the Rolandic region; in the fingers, wrist, thumb, or shoulder, indicating the middle portion; or in the toes, ankles, or leg, indicating the upper portion of the central convolutions (see fig. 1).

The muscular spasm usually spreads rapidly over the whole half of the body and may extend to the other side and become general. Consciousness may remain throughout the fit, especially if there is not much spread. When both sides of the body are involved in the muscular spasm, consciousness is lost. It is important to determine the state of the parts affected after the convulsion, and to note whether there is paresis or anaesthesia. Destructive lesions produce usually a monoplegia; thus monoplegia cruralis, brachialis, and facialis are especially symptomatic of tumour. As the tumour grows the paralysis may increase, and the monoplegia become a hemiplegia. Sometimes with the hemiplegia there is a blunting of sensibility, especially of the sense of touch and the sense of position.

Pre-frontal Region.—A tumour situated in the frontal lobe of the left hemisphere may cause aphasia (partial or complete) when Broca's convolution is involved. Again, from proximity to the motor area, the tumour may give rise to cortical epilepsy. Tumours which grow from the orbital surface of the left frontal lobe may attain a considerable size without giving rise to any affection of speech. It is to be remarked that sometimes the speech-affection arising from a tumour in the left frontal region may take the form of bradylalia. Anosmia from compression or destruction of the olfactory nerve or tract sometimes occurs in tumours of the frontal lobe, and when it can be determined, is of value as a localising symptom. Bruns has pointed out that tumours of the frontal lobe often cause ataxy of the cerebellar type, and thus tend to simulate cerebellar tumours, but this form of ataxy is frequently associated with monoparesis or hemiparesis. Optic neuritis occurs late in the course of the disease, whereas mental dulness, stupor, and a condition resembling imbecility are early symptoms (fig. 2).

Parieto-occipital region.—Tumours often attain a considerable size in this region without producing definite localising symptoms. When the tumour is situated in the left hemisphere, involving the angular gyrus, word-blindness and mind-blindness may occur. If it be situated in the occipital lobe, causing destruction of the optic radiations or the centre for half-vision, hemianopsia would be the result; or if it were an irritative lesion, starting in the meninges, it might give rise to unilateral visual hallucinations.

Temporal lobe.—Important localising symptoms only arise when the tumour is situated on the left side; if it affects the posterior two thirds of the first temporal convolution, word-deafness, amnesia, or paraphasia may result. Occasionally auditory hallucinations occur in irritative lesions of this region.

Parietal lobule.—Tumours in this portion of the brain may cause compression of the Rolandic area, with resulting motor irritation or paralytic phenomena, accompanied by disturbances of sensibility and of the sense of position.

Corpus callosum.—The symptoms of tumours in this situation are not very definite, but, according to Bristowe, the following symptoms indicate a tumour in this region: (1) disturbance of intelligence or stupor, combined with a non-aphasic disturbance of speech; (2) absence of cranial nerve-affections; (3) hemi-parietic phenomena combined with a less-marked paresis of the other side of the body; (4) gradual progressive increase of these symptoms; (5) absence, as a rule, of the general symptoms of tumour.

Basal ganglia.—Tumours in the *corpus striatum* may occur without producing any definite symptoms,

but hemiplegic symptoms may be produced owing to direct or indirect involvement of the internal capsule. Tumours of the *optic thalamus*, for the same reason, usually give rise to hemiplegia frequently associated with hemi-anæsthesia, hemiathetosis, and sometimes hemianopsia, from involvement of the optic radiations.

Tumours of the *third ventricle* may present no definite localising symptoms, but the general symptoms may be very manifest, such as amaurosis, headache, dulness, stupor, and vomiting, due as a rule to internal hydrocephalus. In four cases of tumour of the third ventricle recently seen by the writer, the symptoms were recurrent attacks of drowsy stupor, which sometimes deepened to coma, preceded by restlessness and sometimes by convulsions, general muscular weakness, progressive mental enfeeblement, and optic neuritis.

Cerebellum.—The symptoms of tumours in this situation are ataxy, characterised by a peculiar oscil-

FIG. 2.—Fibro-endotheliomatous tumour growing from the Dura Mater, and pressing on the Frontal Convolution. There was no paralysis during life, nor were signs of intra-cranial pressure observed, probably owing to the very slow growth. Patient was subject to fits and was demented.

lating gait, like that of a drunken man, nystagmus, vertigo and tendency to fall in one direction; muscular weakness on the same side as the lobe of the cerebellum affected; headache, especially over the back of the head, combined with stiffness and rigidity of the neck. Vomiting and slow pulse usually occur. Whereas optic neuritis usually occurs early and is very marked, mental symptoms in the form of apathy, dulness, and stupor develop late, affording thus a contradistinction to frontal tumours.

Tumours of the *base of the brain* are frequently met with. They are usually syphilitic, sarcomatous, or tubercular, but a number of rare tumours may also arise, especially in the neighbourhood of the pituitary fossa. It has already been stated that aneurysms commonly affect vessels of the base of the brain, and may consequently cause symptoms resembling those of a tumour situated in this region.

According to the seat of the tumour and its size, so various structures about the base of the brain are affected, and it is not surprising to find that among the commonest symptoms of tumours in this situation are paralyses of the cranial nerves. The nerves

supplying the eye-muscles are especially liable to be affected, causing various forms of squint and double vision, and ptosis associated with paralysis of the sphincter of the iris, if the third nerve is involved. The optic tract may be compressed and cause hemianopia; or there may be pressure on one optic nerve, when there will exist unilateral symptoms and changes in the fundus oculi; or the optic chiasma may be compressed, as frequently occurs in tumours of the hypophysis cerebri, resulting in bi-temporal hemianopia. If the fifth nerve is involved, there is unilateral anaesthesia of the face, loss of taste and smell on one side, and sometimes sloughing of the cornea. The facial nerve may be affected, and usually the auditory is associated in the destructive process, deafness and peripheral facial paralysis resulting. In such case the muscles of the upper part of the face will be involved as well as the lower; the eye will remain open in sleep, and the muscles will show qualitative and quantitative alterations in the electrical reactions. Some degree of pressure upon the crus, pons, or medulla may be associated with these cranial nerve-paralyses, causing weakness or paralysis of one or both sides of the body, from pressure upon the pyramidal systems of fibres.

Crura cerebri or corpora quadrigemina.—A tumour in this situation is very liable to involve one or more of the nuclei of origin of the third nerve, or the nerve itself. The so-called 'syndrome of Weber' may occur, namely, paralysis of the motor oculi of the side on which the growth is situated, and complete hemiplegia of face, tongue, and limbs of the opposite side. If the corpora quadrigemina are involved, there is usually loss of pupil-reaction, nystagmus, and ataxy.

Pons and Medulla.—Tumours of the pons may be unaccompanied by optic neuritis. Paralyses of the cranial nerves of one or both sides having their nuclei of origin in this situation, associated with paralysis or paresis of the face and limbs according to the size and seat of the tumour, indicate affection of this region. Especially characteristic is the alternate hemiplegia, in which the facial, abducens, and trigeminal nerves, or one of these nerves on one side and the limbs on the opposite side, are paralysed. When there is double hemiplegia, there is usually dysarthria and dysphagia.

Medulla.—Tumours of the medulla may produce symptoms somewhat similar to those of a tumour affecting the lower part of the pons, except that the eighth to the twelfth cranial nuclei may be damaged and cause deafness, dysarthria, dysphagia, aphonia, disturbances of the heart's action and of the respiration, with hicough, and (in many cases) glycosuria. The limbs may be paralysed on one or both sides, and sometimes there is cerebellar ataxy.

DIAGNOSIS.—Three points must be considered: (1) The existence of a cerebral tumour; (2) its situation; and (3) its probable nature. The existence of a tumour is probable when there are severe headache, characteristic vomiting, optic neuritis, and slow pulse. The situation must be inferred from the consideration of the localising symptoms already discussed, and the nature of the growth may be sometimes correctly diagnosed or guessed at by considering the history of the onset and progress of the disease, together with the previous health, sex, and age of the patient. A number of cerebral tumours, e.g. psammoma, lipoma, cholesteatoma, and cysts may remain latent,

and give rise to hardly any symptoms. When a patient comes complaining of severe and continuous headache, the possibility of a tumour must be considered, and an examination of the fundus oculi should always be made. Should neuritis be found to be present, it is necessary to exclude other possible causes, e.g. meningitis, cerebral abscess, hydrocephalus, and nephritis, for some forms of Bright's disease are associated with severe headache and retinitis. It is necessary to remember that in marked chlorotic anaemia, a patient may suffer with severe headache, and an examination of the fundus may even reveal in rare cases neuritis. In chronic lead-poisoning, many symptoms occur which might lead to a mistaken diagnosis of tumour: thus, there may be headache, optic neuritis, and cortical epilepsy. Migraine, hysteria, or neurasthenia may be the cause of severe headache, but the headache in these affections is profoundly influenced by psychical conditions, and may even disappear when the attention is diverted. Stupor, drowsiness, progressive dementia, and attacks of maniacal excitement or melancholia may occur in patients suffering with tumour, and lead to their being certified as insane.

A tumour with focal symptoms, causing Jacksonian epilepsy, must be differentiated from uraemia, alcoholism, lead-poisoning, syphilitic and tubercular meningitis-encephalitis, and in rare cases chronic brain-softening, all of which affections may be attended by convulsive epileptiform seizures. Absence of the general symptoms of tumour, and the history of the case and its progress, will help in coming to a decision; and it is especially in such cases that tenderness and alteration of the note on percussion will be valuable as an aid to diagnosis. In dementia paralytica the patient often complains of headache, and he may be the subject of unilateral fits, but it is very seldom that an examination of the fundus oculi reveals any optic neuritis.

In general paralysis of the insane a sluggish reaction of the pupils to light or the Argyll-Robertson pupil is seldom absent.

COURSE AND PROGNOSIS.—The course of the disease is usually chronic and may extend over years. Some forms of tumour are slower in growth than others, e.g. glioma, osteo-sarcoma, and 'solitary tubercle'; others, e.g. the soft sarcomata and carcinomata, are very rapid. If syphilis can be excluded, the prognosis is most unfavourable. As a general rule, death takes place in one or two years, but occasionally tubercular tumours become stationary, and even undergo regressive metamorphosis. When once the symptoms have become pronounced, death usually takes place in a comparatively short time from exhaustion, coma, or some intercurrent disease, but it may be sometimes quite sudden and unexpected. Some forms of tumour, e.g. angioma, cholesteatoma, and glioma, may remain latent for many years, and then an acute onset of symptoms which rapidly terminate fatally may arise.

TREATMENT.—*General Management.*—It is well in all cases to try mercurial inunction and large doses of iodide of potassium upon the chance that the tumour may be syphilitic. In some cases mercurial inunction over the painful spot on the head may give relief. Allen Starr recommends large doses of iodide of potassium in non-syphilitic tumours, and he has recorded cases which have apparently derived much benefit from heroic doses of this drug. He has given as much as 250 grains

a day. If the tumour is suspected to be tubercular, treatment usually adopted for this disease may be tried, such as cod-liver oil and tonics. Again, liquor arsenicalis as a nerve-tonic may be prescribed. All these remedies however are as a rule of little use, and, unless operative procedure be adopted, the most that can be done is to treat the symptoms and relieve the sufferings of the patient. As already pointed out, most of the drugs which are used for the relief of headache (phenacetin, antipyrine, exalgin, &c.) are of little use, and the only remedy which is of service is morphine or some preparation of opium. The patient may have either hypodermic injections of morphine or some preparation of opium administered internally. Gowers recommends cannabis indica as a narcotic. Leeches to the painful part, also ice-bags accompanied with hot bottles to the feet, and purgatives may help to relieve pain by drawing the blood from the head and relieving intra-cranial pressure. The convulsions as a rule are not relieved by bromides; chloral hydrate appears to be more effective, and inhalations of chloroform in some cases have to be resorted to. The vomiting may be most troublesome, and may necessitate feeding by nutrient enemata. Ice can be ordered to be sucked, opium given, and rest in bed upon the back should be enjoined.

Operative Measures.—The results are not so satisfactory as at first this branch of surgery promised. Many patients die of shock. In only a limited number of cases can the tumour be removed without risk of return, and, not infrequently, the patient is left paralysed, speechless, or mentally afflicted. If the wound becomes septic, hernia cerebri or meningitis is very likely to occur. In recommending operation all these facts should be taken into account, and the surgeon should be guided by the following considerations: (1) that, according to the statistics of Allen Starr, only 7 per cent. of cerebral tumours are suitable for operation, (2) that it is difficult to be sure of correct localisation, (3) that if the patient is suffering from severe symptoms arising from intra-cranial pressure, although it may be impossible to remove the growth, many of the distressing symptoms of the disease may be relieved by operation. If operation is decided upon, its early performance is advisable, and it is essential to success that it should be done in a hospital, and only by those who have had considerable practice in the performance of such operations. In this way delay is avoided, shock, which is the most dreaded feature, is obviated, and complications and hæmorrhage are more skilfully met.

FREDERICK W. MOTT.

BRAIN, Ventricles of, Diseases of.—See VENTRICLES OF BRAIN, Diseases of.

BRAIN, Vessels of, Diseases of.

1. **Aneurysm.**—The larger arteries of the brain, and their minute branches in the cerebral substance, are both liable to aneurysmal dilatation. The 'miliary' aneurysms on the smaller branches within the brain, which are the cause of cerebral hæmorrhage, are described later.

(a) *Aneurysm of the larger cerebral arteries* is more common than that of those of a similar size elsewhere. The large vessels of the base, or their primary branches, may be affected. The basilar and middle cerebral arteries are those most frequently diseased, aneurysms of these two vessels

constituting more than half the cases. Next in frequency is the internal carotid. The vertebral, anterior and posterior cerebrals, anterior and posterior communicating, and anterior cerebellar arteries are occasionally, but less frequently, affected. In one or two recorded cases the aneurysm has been situated in the interior of the pons Varolii or cerebellum. The disease is rather more frequent on the left side, but this is chiefly due to the greater proclivity of the left middle cerebral compared with the right, a fact which is explained by the ætiology. There is occasionally more than one aneurysm, situated on different arteries, or on different branches of the same artery. The aneurysm is usually sacculated, rarely dissecting. Its size usually varies from that of a pea to that of a hazel nut, but aneurysms have been met with as large as a hen's egg. When the size is considerable the brain-tissue is pressed upon and softened, as by any other kind of tumour.

ÆTIOLOGY AND PATHOLOGY.—These aneurysms are rather more common in men than in women, after actual childhood, and are far more frequent before the ordinary degenerative period than aneurysms elsewhere. Nearly half the recorded instances have occurred between ten and forty years of age, and about one-sixth between ten and twenty. The change in the arterial wall resembles that giving rise to aneurysm elsewhere—a fibroid degeneration, with loss of muscular and elastic tissue. Distensible tissue, which yields permanently before the blood-pressure, is substituted for the resilient elements of the wall, which, normally, bring back the vessel to its previous size after each expansion. The alteration is occasionally part of a widely spread arterial change, but more frequently is local. It is then due to some local morbid process, usually one of three kinds: (1) syphilitic disease, which has altered the wall, but has not obliterated or greatly reduced the lumen of the vessel; (2) injury—a blow or a fall on the head, which probably acts by causing a local periarteritis, since extensive traces of old inflammation are sometimes found in the neighbourhood of the aneurysm in such cases; (3) incomplete embolism, imperfect occlusion of the vessel by a plug, from a valve affected with active endocarditis. This cause explains the greater frequency of aneurysm in the left than in the right middle cerebral artery (since this is more prone to embolism), and also the fact that those who suffer from cerebral hæmorrhage at an earlier age than degeneration occurs usually have valvular disease of the heart: in such cases an aneurysm is often found. Whatever be the cause of the alteration in the arterial wall, the efficient agent in the production of the aneurysm is the high blood-pressure in the cerebral arteries, coupled perhaps with a slighter external support than is possessed by the vessels in other parts. See ANEURYSM.

Rupture has occurred in more than half the recorded cases of cerebral aneurysm, and probably occurs in a much larger proportion, since a small aneurysm is easily overlooked in a large extravasation. The blood may escape rapidly or slowly, and the hæmorrhage may take place into the subarachnoid space, or into the adjacent cerebral substance. In the former case, meningeal hæmorrhage is the result. Rupture into the cerebral substance is not uncommon. An aneurysm in the fissure of Sylvius may cause a hæmorrhage into the substance of the brain, ultimately bursting into the lateral

ventricle; and an aneurysm on the posterior cerebral artery may burst into the substance of the pons. Two causes may determine this rupture into the substance of the brain—first, thickening of the subarachnoid tissue adjacent to the aneurysm, and especially over it, hindering its rupture outwards; secondly, the small size of the opening and consequent gradual escape of the blood, producing a slow disintegration of the brain-tissue, in the direction of least resistance. The amount of blood which is effused is often very large, and may make it uncertain from what artery it has come, and the difficulty of discovering an aneurysm is thereby increased. In rare cases a communication forms with a venous sinus, and constitutes an arteriovenous aneurysm. This has occurred between an aneurysm of the internal carotid and the cavernous sinus.

SYMPTOMS.—Symptoms of the existence of an aneurysm may be entirely absent. When present, they depend on the pressure which the tumour exerts on neighbouring parts. They vary widely according to its seat, and they are rarely by themselves distinctive. Mental disturbance is uncommon. Headache is a very frequent symptom. It is often intense, sometimes throbbing, and may be localised, as to the occiput in basilar aneurysm. Giddiness is not uncommon, and is complained of in aneurysms in all situations. Convulsions are not frequent except in cases in which the aneurysm is in the neighbourhood of the motor region of the cortex, i.e. is on the middle cerebral artery or its branches. Palsy in some situation often occurs, and depends on the pressure of the tumour; the most common is that of the cranial nerves which lie adjacent to an aneurysm at the base, as of the nerves of the orbit in aneurysm of the internal carotid. Optic neuritis is only occasionally present. The symptoms are thus those of an intracranial tumour, and they suggest an aneurysm when they are such as to show that the tumour is in the position of one of the arteries liable to be affected; and the probability is increased if one of the known causes of aneurysm can be traced. If there is a history of syphilis the diagnosis lies between an aneurysm and a gumma, and the former is only probable if the symptoms are not lessened by appropriate treatment. The presence of heart-disease has less often definite diagnostic importance than its causal relation might suggest, because embolic aneurysms usually rupture before causing pressure. Injury, it must be remembered, may also cause a neoplastic tumour. Aneurysms elsewhere would, of course, give great additional significance to the symptoms, but the coincidence is too rare to be of practical importance. In some cases a murmur can be heard by the patient, and in still rarer cases (of aneurysm of the internal carotid) it has been audible on auscultation. But even an objective murmur, alone, cannot afford actual proof of the existence of an aneurysm, since pulsation, the chief sign of an accessible aneurysm, can never be perceived.

Rupture of an intracranial aneurysm gives rise to symptoms which vary according as the blood escapes quickly or slowly. If quickly, the blood usually passes into the meninges and causes sudden apoplexy with general paralysis, rapidly deepening to a fatal issue. If slowly, the symptoms are less sudden, and unilateral paralysis or convulsions may occur. This is especially the case when the blood escapes

slowly into the cerebral substance; the unilateral symptoms commence suddenly, and gradually increase during a few hours or days, with or without initial loss of consciousness, but ending in fatal coma.

TREATMENT.—Little can be done in cases where intracranial aneurysm is suspected. Even when it is of syphilitic origin, drugs are powerless to alter the damaged and dilated vessel, since the change which has given rise to it is of the nature of a cicatricial transformation of the syphilitic tissue, on which drugs can no longer exert the influence they possess over the earlier stages of the growth in the wall. Hypodermic injection of ergotin ($\frac{1}{8}$ -grain) has been recommended by Langenbeck and others. Iodide of potassium may also be given in the hope of promoting coagulation within the sac, from the undoubted evidence of the power it has to effect this in aneurysms elsewhere. This is also true of the hypodermic injection of a solution of gelatine, if its alleged influence is confirmed (*see* HYPODERMIC MEDICATION). Rest is important. All causes of increased intravascular pressure, such as effort and low positions of the head, are to be avoided. The bowels should be kept regular. In rare cases where progressive paralysis of orbital nerves suggests the probability of aneurysm of the internal carotid, and a murmur renders the diagnosis certain, ligature of the common carotid may be, and has been, resorted to with success. It is, moreover, probable that intracranial surgery may be able to cope with aneurysms on some other vessels, but on this point experience is still to be gained.

(b) *Minute 'miliary' aneurysms* occur in the small arteries of the pia mater and substance of the brain, and are the chief cause of cerebral hæmorrhage. They are met with almost exclusively in the second half of life, and increase in frequency with age up to about seventy-five, the less frequency of cerebral hæmorrhage in extreme old age making it probable that they are less common in very late life. They may involve vessels not more than the $\frac{1}{100}$ inch in diameter, but are most common on vessels a little larger than this. The walls suffer fibroid degeneration of the outer and middle coat, commencing, it is said, as nuclear proliferation. The muscular tissue of the middle coat disappears, and distensible tissue replaces it. Hence under the influence of the blood-pressure, which is high in the arterioles prone to be thus changed, the artery at the spot becomes dilated into a sacculated aneurysm, varying in size from the $\frac{1}{25}$ to the $\frac{1}{35}$ of an inch. These dilations have been found in all parts, but most frequently in the central ganglia, and next most frequently in the pons Varoli, the convolutions, the cerebellum, the medulla oblongata, the cerebellar peduncles, and the centrum ovale. They are to be found in most cases of cerebral hæmorrhage; and it is probable that such hæmorrhage is due to their rupture. Similar minute aneurysms of the retinal arteries have been observed to co-exist in rare cases.

The rupture of a minute artery into its perivascular sheath distends this with blood, causing what has been termed a minute dissecting aneurysm. Such are frequently met with in cases in which the vessels are exposed to extreme pressure, as in death from asphyxial conditions; or in the increased tension in collateral vessels when vascular obstruction has occurred.

SYMPTOMS.—No symptoms are known to be

associated with the existence of these minute aneurysms, and this fact explains the absence of premonitory indications of a liability to cerebral hæmorrhage. The symptoms of rupture are described under BRAIN, Hæmorrhage into.

2. **Degeneration.**—(a) *Of Arteries.*—The larger cerebral arteries are very common seats of degenerative changes which are fully described in the article on ARTERIO-SCLEROSIS. The cerebral arteries, however, are peculiarly liable to these changes. The cause of this liability is probably the strain to which the badly supported cerebral vessels are exposed in consequence of their direct origin from comparatively large vessels, rendered more effective by the deficient support from adjacent structures. This deficiency increases as life goes on, because the atrophy of the brain-substance leads to an increase in the size of the peri-arterial spaces. It is not easy to explain the occasional freedom of these vessels from atheroma when this is abundant elsewhere.

Degeneration of the cerebral vessels may lead to anæmia of the brain, rupture of the vessels, or thrombosis in their lumina. Anæmia has already been considered (*see* BRAIN, Anæmia of); rupture and thrombosis will be dealt with in the present article.

SYMPTOMS.—Atheroma of the cerebral vessels leads to the symptoms of local anæmia of the brain, and is a common cause of the transient cerebral symptoms so frequent in the old, before a definite seizure occurs. Tingling in the limbs of one side, and slight loss of power, as well as more general symptoms, as headache, may be thus produced, and are frequently the precursors of an attack of hemiplegia from the closure of the vessel. It is possible also that the loss of memory and mental failure common in the old may be the result of more general interference with the supply of blood to the brain in consequence of this arterial disease, but, without symptoms of sudden onset, it is more often due to senile failure of cerebral nutrition.

TREATMENT.—Tonics, especially cardiac, and substances which, as cod-liver oil, promote the nutrition of the tissues generally, may be given with possible advantage. It is not likely, however, that any treatment can modify the state of the arterial wall, or that its tissue ever resumes, in any degree, its normal characters. The maintenance of the general nutrition in a good state may lessen the tendency to fatty degeneration and subsequent calcification of the tissue, and thus postpone or prevent the disastrous consequences of occlusion of the vessels. In this, however, we can only adjust our treatment on rational grounds, since the nature of the case precludes any possible evidence of beneficial result. Of especial importance is it, in any case in which there is reason to believe or to suspect the presence or future development of atheroma, to do all in our power to keep the arterial tension within normal limits, and to preserve the blood from the presence of the products of imperfect digestion and the accumulation of metabolic products, which favour thrombosis. It is important to adopt in the old a regimen and treatment likely to lessen the gouty tendency which so often attends atheroma and often increases the tendency to thrombosis.

(b) *Of Veins.*—Degeneration of the walls of the veins is much less frequent than degeneration of the arteries, perhaps on account of the less degree of pressure to which they are exposed. Disease of

their walls is generally the result of inflammation spreading from without. Thrombosis in them may thus result from adjacent inflammation, tubercular or other. Occasionally the veins of the pia mater may be found varicose in advanced life, and in one case rupture of such a dilated vein was the cause of meningeal hæmorrhage.

3. **Embolism.**—**DEFINITION.**—The obstruction of arteries or capillaries of the brain by solid particles carried by the blood-current from some other part of the vascular system.

ÆTIOLOGY.—The source of the embolic particles is almost invariably situated between the pulmonary capillaries and the obstructed vessels, i.e. in the pulmonary veins, the left side of the heart, or the arteries. In arterial embolism it is necessarily so, since no particles large enough to obstruct even a small artery could pass through the capillaries of the lungs. In almost all cases the heart is the source of the plug, a particle of fibrin being washed by the blood from a deposit on a diseased valve or in some recess (as the auricular appendix). Endocarditis, or chronic valvular disease, therefore, usually co-exists with the embolism. Mitral stenosis is an especially frequent source of emboli, probably because the surface is commonly much altered, and the blood-current is in part slow (in diastole, allowing deposit), and in part very rapid (in auricular systole, detaching loose particles). Moreover the dilatation of the left auricle, and the imperfect degree in which the blood is expelled from it, frequently lead to a coagulum in the appendix. Disease of the aorta—atheroma or aneurysm—is the next most frequent source, and, less frequently, disease of the carotid or vertebral arteries, and coagulation in the pulmonary veins, large or small—the latter in some rare cases of inflammation and growths.

Particles obstructing capillaries may come from some softened atheromatous patch or fibrinous deposit, from pigmentary formations, or from deposits in ulcerative endocarditis. In the last case the obstructing material has a septic character, probably due to bacterial organisms, and the inflammation it causes may be suppurative.

Embolism occurs with equal frequency in both sexes, and at all periods of life, but most frequently between later childhood and middle life. This is explained by the fact that it occurs more readily from valvular disease due to endocarditis than from that which results from the degeneration of age, but most frequently when the lapse of time has led to secondary changes in the valves damaged, or during second attacks of endocarditis—inflammation of valves previously diseased being especially prone to give rise to embolism. Hence most subjects of embolism have suffered or are suffering from one of the diseases known to cause endocarditis, especially from rheumatic fever, occasionally from chorea or scarlet fever.

ANATOMICAL CHARACTERS.—Almost any of the cerebral arteries may be obstructed; but the vessels most prone to suffer are the middle cerebral, in consequence of the more direct course of the circulation to them. Next in frequency are the internal carotid and the anterior cerebral. Embolism is less frequent in the arteries to which the vertebrals convey blood, but has been met with in most of them; even the basilar may be obstructed by a clot small enough to pass through the vertebral, but too large to enter the posterior cerebral.

The cerebellar arteries are those less frequently affected. Obstruction of several vessels is sometimes found, having occurred at the same or different times. Embolism is more common on the left side, but the difference is not so great as is often stated, being not greater than as four to three. It is due to the more direct origin of the left carotid, into which a plug can therefore be more easily carried than into the right; hence it depends on the greater frequency of the occlusion of the branches of the internal carotid, and especially (because it is the vessel most often affected) of the middle cerebral. The left vertebral is also rather more often plugged than is the right, but embolism of this artery is too rare materially to influence the numerical relation between the vessels of the two sides in their liability.

The plug is usually arrested at some spot at which the vessel is narrowed by a branch being given off. Here the fragment may be found, usually decolourised, and commonly closing altogether the lumen of the vessel. On each side of this is a secondary clot, distinguished by its darker tint: the distal extends far into the contracted branches of the vessel, the proximal as far as the next large branch. The obstruction may lead to inflammation of the wall of the vessel at the spot, especially when the plug has been carried from a place at which inflammation is going on. The inflammation leads to change of texture and degeneration, fibroid or fatty; the former, when the obstruction is incomplete, may permit an aneurysm to be formed, the latter may cause a thickened patch, in which calcification may occur. The inflammation may spread to the adjacent tissue, leading to induration around the spot. It is most intense when the plug comes from a valve the seat of active endocarditis, and may then determine a peculiar irritative character in the secondary inflammation, as is shown by the fact that optic neuritis sometimes develops in such cases.

The effect of embolism is to arrest the blood-supply to the part of the brain to which the artery is distributed, unless the blood can reach it by some other channel; the cerebral tissue, deprived of its nutrition, undergoes necrosis and softening (*see* BRAIN, Softening of). This result, however, is often prevented by the anastomoses that exist in many parts, and as these are very irregular in the cortex of the brain, both in different persons and in different parts of the same arterial area, considerable variations exist in the extent of softening that results from occlusion of the same artery. But in the central ganglia anastomoses are absent, and softening uniformly follows. Thus embolism of the trunk of the middle cerebral may cause softening of the corpus striatum, while the cortex supplied may be intact, or softened in irregular areas, or it may be totally destroyed. Capillary embolism also causes softening, and when the obstruction is from a septic source, the inflammation adjacent may be suppurative, and 'metastatic abscess' may result. Thus cerebral abscess results from suppurative disease in the thorax and other parts. One of the rare curiosities of pathology is the production of such abscess by the embolic obstruction of the vessels with fragments of *Oidium albicans* gaining access to the circulation from the throat. A plug of fibrin lodging in an artery sometimes quickly breaks up, and is carried into the

capillaries, so that the artery is pervious, although the brain-tissue it supplies is necrosed. Necessarily, when the capillaries are obstructed, a collateral blood-supply is of no avail to prevent softening.

For the SYMPTOMS, DIAGNOSIS, and TREATMENT of cerebral embolism, *see* BRAIN, Softening of.

4. **Rupture.**—Rupture of cerebral arteries is common and is the cause of cerebral hæmorrhage; rupture of capillaries is not infrequent. Rupture of veins is extremely rare, except as the result of injury.

(a) *Of Arteries.*—The proximate causes of rupture are weakening of the arterial wall, and increased pressure within the vessel. The conditions which give rise to these two factors are the remote causes of rupture. The actual rupture is often due to a temporary sudden excess of intravascular pressure, but this often does not immediately precede the symptoms, which are only manifest when the initial opening in the wall has increased.

ÆTIOLOGY.—The wall of the vessel is weakened, especially by degenerative disease. Aneurysmal dilatation and thinning have usually resulted from the chronic change. In some diseases attended with a tendency to extravasation (purpura, hæmophilia, &c.) it is probable that the vascular walls undergo rapid degeneration in the acquired, and are unusually thin in the congenital maladies. Defective external support, from atrophy of the brain, causing increased size of the perivascular canals, was formerly thought to be a potent cause, and is now perhaps underrated. The mobile perivascular fluid which surrounds the vessels must afford a less efficient support than cerebral tissue, and sudden variations in the size of these canals will expose the vessels to sudden differences in the amount of tension to which their walls are exposed.

When vessels are much weakened, they may rupture when the intravascular pressure is at, or even below, the normal; very commonly, however, there co-exists increased pressure. Loss of arterial elasticity leads to less equable pressure. Arterial degeneration, and still more constantly the contraction of the minute arterioles, in Bright's disease, cause increased tension by obstruction; and the hypertrophy of the heart, which develops to overcome the obstruction, adds materially to the pressure within the arteries. Hypertrophy to overcome an obstacle near the heart has probably no influence in causing rupture of cerebral vessels.

The immediate cause of rupture is generally some temporary increase of the blood-pressure due to effort—as in cough, straining at stool, or vomiting; excited action of the heart due to exertion or emotion; suddenly developed heart- or lung-disease obstructing the circulation; local obstruction to return of blood; or the action of gravitation in the recumbent posture. The last cause probably determines the frequent occurrence of rupture during sleep in which contraction of the arterioles is probably added.

The conditions which produce these proximate causes are the remote causes of rupture. The most efficient are those which lead to arterial degeneration (*see* ARTERIO-SCLEROSIS). In addition to these certain local considerations must be borne in mind. The position of degeneration is probably largely influenced by the distribution of the vessels; and the latter may be hereditary, as the retina

sometimes strikingly shows us: the same arrangement of the branches of the retinal artery may be seen in parent and child. So, too, correspondence in the way in which the cerebral arteries of the two sides divide and are distributed may be observed to coincide with a close correspondence in the position of spots of visible degeneration, and doubtless also determines a like symmetry in the invisible degeneration of the minute aneurysms; hence rupture sometimes occurs at the same place in each hemisphere.

Some of the cerebral arteries give way more frequently than others, especially the arteries of the corpora striata and pons Varolii. This seems due (1) to their direct origin from vessels of very considerable size (basilar and middle cerebral), and their consequent exposure to the full pressure within the parent-trunk; and (2) to their 'terminal' character, which precludes collateral relief when a general increase of intra-arterial pressure augments disproportionately that in an artery in which it is normally above the average for the size of the vessel. One artery, which very frequently gives way, passes from the middle cerebral through the anterior perforated spot, onwards between the island of Reil and the lenticular nucleus, the outer part of which it perforates, and then passes through the white fibres of the 'internal capsule,' between the lenticular and caudate nuclei, to ramify in the anterior part of the latter. The arterial branches supplying the convolutions on the surface of the brain are not often ruptured, except from injury. They are exposed much less directly to the blood-pressure, and sometimes possess considerable anastomoses.

SYMPTOMS.—The consequence of rupture of an artery is cerebral hæmorrhage, the symptoms and treatment of which are described elsewhere (see BRAIN, Hæmorrhage into; and BRAIN, Injuries of).

(b) *Of Capillaries.*—The minutest vessels and the capillaries rarely rupture, except when exposed to sudden pressure by venous thrombosis; the obstruction in the minute vessels from which the vein carries away the blood may determine numerous capillary hæmorrhages into the cerebral substance. In general intense venous congestion, as in asphyxial states, such hæmorrhage may occur; and a more frequent result is extravasation into the perivascular sheath, which thus becomes distended with blood.

(c) *Of Veins.*—Rupture of veins is only the result of intense mechanical congestion, such as violent paroxysms of whooping-cough or intense asphyxia, as from a violent epileptic fit. The effects are the symptoms of a local cerebral lesion especially of the cortex, sometimes perhaps of the cerebellum.

For SYMPTOMS see BRAIN, Hæmorrhage into.

5. **Syphilitic Disease.**—See BRAIN, Syphilis of.

6. **Thrombosis.**—Thrombosis is the coagulation of the blood *in situ*. It may occur in the cerebral arteries, or in the cerebral veins and sinuses.

(a) *In the Arteries.*

ÆTIOLOGY.—The causes of arterial thrombosis are considered in the article on THROMBOSIS.

ANATOMICAL CHARACTERS.—The arteries occluded may be one or several, large or small. Thrombosis occurs most frequently in the internal carotid, middle cerebral, vertebral, and basilar arteries, or their branches. It is not uncommon for a clot to form in a branch that comes off at a diseased spot, while the main artery continues pervious. The orifice of the branch is narrowed so that enough blood does not enter to maintain the circulation in

the part beyond. The wall of the artery at the seat of the thrombosis may present any of the local causal conditions mentioned elsewhere, or, rarely, it may be healthy. After a time thickening from secondary arteritis occurs. Within the vessel is a coagulum which usually fills its interior, and is adherent to the wall. It sometimes does not fill the vessel, either because originally incomplete, or because the clot has shrunk. A recent quickly formed coagulum is red, but after a time it becomes pale and yellow. A slowly formed coagulum is pale, and may be laminated. A secondary clot usually forms far into the contracted distal branches, and on the proximal side as far as the nearest large branch. The clot after a time may undergo calcification, or, with the artery, contracts and shrinks to a cord. The brain-tissue, to which the artery was distributed, is at first anæmic, but quickly becomes the seat of congestive stasis and undergoes softening—red, yellow, or white, according to the amount of vascular distension and blood-pigment remaining in it. If the collateral circulation is free, it may remain unsoftened, and scattered areas may escape from this cause, in the region supplied.

SYMPTOMS.—Where chronic arterial disease is the cause of thrombosis, it may be preceded by the symptoms of local cerebral anæmia (see BRAIN, Anæmia of). The thrombosis itself leads to the symptoms of loss of function in the part to which the artery passed. The onset of these symptoms is slow or sudden, according to the rapidity with which the coagulum forms; and their degree depends on the size of the vessel occluded, its position, and its relation to other vessels which may supply blood to the area involved. Thrombosis of a small vessel in the cerebral substance usually leads to transient brain-disturbance, headache, vertigo, tingling, and temporary weakness in the limbs, soon passing away if a collateral circulation is established; much more slowly, if softening ensues, by compensatory action elsewhere. The occlusion of a large vessel causes commonly very marked symptoms. Complete hemiplegia is frequent, and its onset may be attended by loss of consciousness. See BRAIN, Softening of.

DIAGNOSIS.—The diagnosis rests on a combination of the symptoms of local cerebral disease with the causal condition—vascular mischief (indicated by probable age, degeneration elsewhere, or syphilis), and with conditions leading to feebleness of the blood-current, and increased coagulability of the blood. The diagnosis is rendered more probable by the symptoms, if slight, being transient, if severe being of gradual onset, and, whether slight or severe, being preceded by the premonitory indications of local cerebral anæmia (headache, and local symptoms in the limbs, &c.).

The **PROGNOSIS** and **TREATMENT** of thrombosis in arteries are considered under the resulting condition. See BRAIN, Softening of.

(b) *In Cerebral Veins and Sinuses.*

ÆTIOLOGY.—Thrombosis in sinuses may be primary, and due to changes in the constitution or the circulation of the blood; or secondary, and due to local causes inducing coagulation directly at the spot affected. Secondary thrombosis is the more common. The same conditions of retarded circulation and altered blood-state which permit coagulation in arteries favour it also in veins, and it is often seen in such conditions as phthisis and cancer, and

especially in marasmic states in children. Hence the primary form is most common in children, but the secondary form occurs with nearly equal frequency through life. Local retardation of the circulation from narrowing of the sinus, or compression of the jugular vein, occasionally assists. The blood-current in the front part of the longitudinal sinus is one of extreme sluggishness, on account of the physical conditions of the circulation. Local change causing coagulation is usually the extension to the sinus of adjacent inflammation, or of a clot produced in a tributary vein by such inflammation. Caries of the bones of the skull, especially of the temporal bone, and meningitis are common causes of thrombosis in adjacent sinuses. Lastly, injuries of the skull involving the sinuses sometimes cause coagulation in them.

ANATOMICAL CHARACTERS.—Of primary thrombosis the superior longitudinal sinus is the most common seat, and thence the clot spreads into the veins on either side, and occasionally also into the lateral sinuses. When secondary, the thrombosis occurs in the sinus nearest to the local disease; in that of the petrous bone, the lateral sinus is usually involved. The sinus is distended by firm clot, commonly (not invariably) adherent, sometimes in concentric layers. The walls of the vessel are healthy when the thrombosis is primary or is secondary by extension of clot, but thickened and brittle when invaded directly by adjacent inflammation. After a time the clot may soften and break down—more quickly in cases in which the adjacent inflammation is of a septic character.

The consequence of venous thrombosis is local arrest of the blood-current, the tributary veins and capillaries becoming enormously distended with blood. Sometimes the smaller vessels may give way, causing numerous minute extravasations; the cerebral substance is then crammed with small hæmorrhagic foci, which often coalesce. The condition is especially seen in the convolutions. Blood is also effused into the meshes of the pia mater, and into the subarachnoid space. Into the looser tissues and into the ventricles serum may escape. Thrombosis of the veins of Galen is one cause of ventricular effusion. Ultimately the brain-tissue undergoes softening, first red, and then yellow or white, as the blood-pigment is slowly removed. Occasionally, in septic cases, the softening of the clot leads to pyæmia.

SYMPTOMS.—The cerebral symptoms produced vary in their character. Sometimes they are at first those of excitement and irritation, namely, intense headache and muscular spasm, manifested by contractions in the limbs, or by convulsion, often beginning locally, according to the position of the secondary congestion. These symptoms, after one or several days, are succeeded by those of depression, with coma, and dilatation of pupils. In other cases the coma may come on suddenly, and the stage of excitement, above described, may be absent or little marked. Now and then hemiplegia comes on slowly, without initial loss of consciousness, and develops to a complete degree in the course of a few hours or a few days. Convulsions, when they occur, often continue till death. When the superior longitudinal sinus is plugged, epistaxis, œdema of the forehead, and exophthalmos have sometimes been observed. When the lateral sinus is obstructed, there may be painful œdema behind the

ear, and the jugular vein on that side has been noticed to be less full than on the other.

DIAGNOSIS.—The diagnosis rests on the occurrence of severe cerebral symptoms in association with a causal condition, constitutional or local. Of the latter, ear-disease and injury are the most important.

PROGNOSIS.—This is always serious, death being, in most cases, speedy.

TREATMENT.—The indications for treatment are for the most part causal. In primary thrombosis stimulants and nutritious diet are necessary, and tonics if they can be taken. The patient should lie with the head and shoulders a little elevated, and care be taken that the neck is not bent, and that there is no constriction of it by tight clothes. In secondary thrombosis, occurring in robust individuals, leeching or cupping may be employed; purgatives should be given; and in the less severe cases a blister may be applied near the probable seat of thrombosis, especially behind the ear, and the utmost care taken to afford free exit for pent-up inflammatory products. Pain and convulsion are relieved most effectually by ice to the head.

W. R. GOWERS.

BRAIN-FEVER.—A name popularly applied to any kind of febrile state in which symptoms of cerebral excitement are prominent; as well as to cases of inflammatory disease of the brain or its membranes.

BRASS-POISONING.—**DESCRIPTION.**—Brass is an alloy of copper and zinc in somewhat variable proportions, generally containing about 70 per cent. of the former metal. Its preparation may be roughly divided into two processes, casting and manufacturing; and the employment of the workman on the first or on the second of these mainly determines the acuteness or chronicity respectively of the ill effects from which he is liable to suffer. In each case, as a rule, the poison is acquired by inhalation—in the acute variety, commonly known as *brass-founder's ague*, by inhaling the fumes given off in the act of casting; and in the chronic form, by the inhalation of the minute particles of triturated brass that permeate the atmosphere of the shops wherein the manipulative procedures are carried out.

Which constituent of the fumes is responsible for the production of brass-founder's ague is a question on which opinions differ, some authorities blaming the copper, and others the zinc; but there is little doubt that in the chronic affection, at least, the principal offender is the copper.

I. Brassfounder's Ague.—This is an acute paroxysmal complaint which attacks the casters or founders, but is not altogether unknown in other departments of the trade. These attacks, though of frequent occurrence, show no tendency to regular periodicity. They generally develop on the first day after a holiday, but they may also be influenced by the direction of the wind or the foggy weather, either of which conditions may retard the escape of the poisonous fumes from the shop.

SYMPTOMS.—Several hours after commencing work, usually in the afternoon of a casting day, the first symptoms begin to make their appearance. These consist of malaise, a sense of fatigue and oppression, and frequently constriction of the chest, accompanied perhaps by nausea and muscular pains. This forms the prelude to a definite cold stage in

which the patient sits shivering and trembling, his teeth chattering, with pains in his head, back, and limbs. With great difficulty he makes his way home to bed, where for hours these symptoms persist, and he is unable to obtain warmth or sleep. Vomiting may or may not occur; but eventually the shivering ceases, the skin becomes warm, and a stage of profuse sweating ensues, in the course of which the patient falls into a slumber from which he awakes in the morning with a feeling of sickness and prostration not severe enough, however, to prevent his returning to work.

II. Chronic Brass-poisoning.—Some persons may be employed for months or years, filing, polishing, or otherwise manipulating brass, even under adverse conditions, without suffering any ill effects; others become affected almost from the commencement of their occupation; while others, again, exhibit symptoms only after many years.

SYMPTOMS.—In most instances, especially in young persons, the complaint is ushered in by *anæmia*. The usual accompaniments of *anæmia*—palpitation and dyspnoea on exertion, dyspeptic symptoms, and *anorexia*—are frequently present in some degree, although not generally very acute. Tachycardia is of fairly common occurrence, while nausea, vomiting, thirst, colic, and constipation are not infrequent (*see COLIC*). Slight indefinite pains of a neuralgic character may be complained of, with headache, accompanied by a sense of weakness, malaise, and nervousness, greater than is generally to be found in ordinary cases of *anæmia*.

A green line upon the teeth may usually be observed before the first symptoms of poisoning appear. This is not diagnostic of brass- or copper-poisoning. It is merely an indication that the individual is in the habit of coming into intimate contact with the metal, and that the process of absorption has commenced. The green line is very distinct. Instead of being situated on the gums like the line in plumbism, it forms a band of varying depth in front of the bases of the teeth just where they emerge from the gums, and is most marked on the teeth of the upper jaw. The colour is usually a brilliant green, but may vary in intensity from a light green to a dark olive.

As the disease advances, the subcutaneous fat gradually diminishes, the muscles atrophy, and a condition of progressive emaciation supervenes, which, in course of time, becomes one of the most marked features of the complaint. There is great loss of strength; and muscular tremors, mainly confined to the hands and the tongue, are of very frequent occurrence. The knee-jerks are normal or slightly exaggerated, except when an actual peripheral neuritis exists. Headache is almost always complained of, as well as pains, very variable in character and situation, affecting the abdomen, legs, back, chest, or other parts. The direct contact of brass-dust with the mucous surfaces produces symptoms of laryngeal or pharyngeal catarrh, with aphonia, sensations of dryness, discomfort, or constriction in the throat, and a metallic taste in the mouth. There may be a dry tickling cough, sometimes accompanied by the expectoration of thick tenacious sputum, and occasionally by hæmoptysis. This chronic catarrh of the bronchial tubes may ultimately end in fibrosis of the surrounding lung-tissue. As a rule the dyspepsia with loss of appetite and gastralgia persists, while sickness and even vomiting are occasionally met with. The tongue is furred,

moist, and tremulous; the bowels are irregular; and the breath emits a disagreeable metallic odour. A feeling of oppression or nervousness, sometimes of a very intense character, is common among such patients, who complain also of repeated attacks of faintness or 'sinking' sensations. Profuse sweatings and sensations of localised coldness, probably of vaso-motor origin, are a prevalent source of annoyance. The sweat is observed to be of a greenish hue by its staining the undershirt green, and the same colour, undoubtedly due to the presence of salts of copper, may be noticed in the grey hair of old workmen, and in the palms of the hands, as well as in the complexion, which is of a peculiarly sallow type, quite different from the wax-like pallor that characterises the premonitory *anæmia*. On various parts of the body may be found itching skin-eruptions of an eczematous or acneiform character, due either to the contact of the skin with brass-dust and sand, or to the salt or salts of copper dissolved and excreted in the sweat. Itching, however, may be complained of without any visible eruption. It is generally believed that brass-workers are peculiarly liable to contract phthisis, and this is probably true; but there is no doubt as to the prevalence of pulmonary fibrosis among this class of operatives. An ataxic form of multiple neuritis due to the action of brass has also been described.

TREATMENT.—**I. Preventive.**—The first consideration, both in the acute and in the chronic variety, is to deal with the cause, and to this end it is necessary that the ventilation of the workshops should be thoroughly efficient. Special Rules, issued by the Chief Inspector of Factories, insist on the provision of suitable exits for the fumes and dust in the mixing and casting shops, on the promotion of cleanliness among the workers, and on the prohibition of eating during the process of casting. Similar regulations are equally necessary in the other departments of brass-working where the atmosphere is laden with finely divided particles of metallic dust. Food should on no account be taken in the workshops, neither should it be eaten with unwashed hands.

2. Remedial.—Milk as a beverage has long been recognised as a corrective. It should be drunk freely both in the chronic form of poisoning and in the 'Ague.' Lobelia and tobacco are reputed to be of value in the treatment of the paroxysms of brass-founder's ague. Abstinence from smoking is recommended until the attack comes on, 'then let him smoke *ad nauseam* the strongest tobacco he can procure.' Other emetics are likewise useful.

For the treatment of chronic brass-poisoning iodide of potassium has been much employed; but phosphorus in doses of $\frac{1}{30}$ grain, or diluted phosphoric acid in fifteen-minim doses, given three times a day, seems to act almost as a specific.

Considering the difference in susceptibility of different individuals to brass-poisoning, it is well to advise any one who shows symptoms either to change his occupation entirely, or at all events to endeavour to get transferred to some other department of the works.

WILLIAM MURRAY.

BREAK-BONE FEVER.—A synonym for dengue. *See DENGUE*.

BREAST, Diseases of.—**SYNON.** : Fr. *Maladies de la Mamelle*; Ger. *Brustdrüsenkrankheiten*.

This subject will be treated under the following divisions:—

I. *Abnormalities and disorders of early life.* II. *Disorders of adult life.* III. *Diseases affecting the rudimentary organ in the male.* IV. *Diseases of the nipple.*

I. **Abnormalities and disorders of early life.**—Although in the human female the breasts are two in number, instances are not wanting of multiplicity. The additional breasts are usually found in the axilla or on either side of the median line. In exceptional and rare instances breasts have been found on the arm, buttock, or outer side of the thigh. Care must be taken not to confound them with lipomata. While supernumerary breasts may swell and contain milk at times of lactation, far more often they are functionless and little more than nipples, or pigmented wart-like spots, with no true gland-substance beneath them. The latter are common, especially in the male, and often pass for moles. Supernumerary breasts in the axilla are generally connected by a string of gland-tissue with the main breasts. When they enlarge at lactation they give rise to alarm: they are sometimes the seat of cancerous and other growths. Occasionally the breasts are absent (*amazia*), and this abnormality may be associated with absence of the pectoral muscle, or part of the chest-wall. On the other hand, the breasts may pass the boundary of physiological increase, and even attain many pounds in weight, so as to form a distressing malady. Enormous increase in the size of the mammae has also been observed in elephantiasis. Hypertrophy of the breasts has been noted in the male (*gynecomazia*). Some of the cases have been associated with malformation of the testes. Enlargement has also been noted in association with pulmonary tuberculosis, and cases are recorded of men who have undertaken the duties of the opposite sex and helped to suckle their offspring.

In the *rudimentary period* of the gland the tissues composing it are rarely liable to morbid derangement. Soon after birth, especially in male infants, the rudimentary nipple and the skin of the region within the zone of the areola become slightly elevated and of a pink hue. In some infants a secretion, slightly milk-like, oozes from the ducts. In this state, rubbing may lead to inflammation and suppuration. When this happens the abscess must be incised and treated on ordinary principles.

II. **Disorders of adult life.**—*About adult age, in both sexes*, when the generative organs approach maturity the breast-gland enlarges, and may be painful, thus causing anxiety to the individual. In the female, the breasts generally develop simultaneously, but exception to this rule need cause no alarm.

As the development of the breast reaches maturity, the gland becomes closely associated with the pelvic generative organs, being tender and enlarged just before each menstrual period.

Neuralgia and disorders of pregnancy.—After conception the breasts begin to enlarge, and minute pisiform indurations may be felt at their borders and on their surface. Very rarely this increase in bulk is attended with considerable reflex pain referred to the back, neck, inside of arms, shoulders, and side of thorax—over, in fact, the area of distribution of the branches of those intercostal nerves which send filaments to the breasts. This state is most likely to occur in a first concep-

tion, and in women of excitable, nervous temperament. Attention to ordinary hygienic measures affords relief to the pain.

Genuine neuralgia of the mammae may be experienced, a severe and distressing complaint, and one difficult to cure. It is often found in women who undergo excessive sexual stimulation without the natural sequence of pregnancy. Such cases are sometimes dependent upon small fibrous tumours, inflammatory areas of thickened tissue, or little cysts. The removal of these cures the pain. In other cases, there is some definite mischief in the pelvic organs of generation to be detected and remedied. In other cases the patient is anæmic or depressed. In the treatment of such cases, iron and blisters, with nourishing diet, are indicated. Galvanism, judiciously employed, is a most valuable remedy in mammary neuralgia.

In large, lax, pendulous breasts, the separate lobes of which each is composed may excite apprehension of the existence of a tumour. But new-growths are so rarely developed during pregnancy, that the greatest caution must be exercised in the diagnosis of their nature.

Very rarely, no change whatever in the breasts accompanies pregnancy (*agalactia*), under which circumstances there is an absence of the secretion of milk after parturition.

Inflammation of the Breast.—Abscess.—**SYNON.:** Mastitis.

ÆTIOLOGY.—Before lactation acute inflammation of the breasts is uncommon: after lactation, it is frequent. The slightest unusual fullness or ‘knottiness’ discovered after the infant has been sucking, and when the ducts and their terminal secreting vesicles should be empty, requires immediate attention. Congestion of a lobule or lobe with milk produces the nodule, and the cause of the impediment to its escape should be sought for. The state of the nipple is generally the origin of the difficulty. In many women the nipple is very small and undeveloped, perhaps only on one side, so that the infant, especially if not very strong, has great difficulty in obtaining sufficient milk, and its efforts cause pain in the part. This circumstance induces the mother to prefer suckling with that breast the nipple of which is perfect, and the infant soon appreciates the advantage of that side. Consequently the gland-tissue of the breast with the imperfect nipple becomes congested. Every time the infant sucks it becomes worse, more and more pain and irritation are excited, the orifices of one or more of the ducts in the nipple become blocked, and perhaps the infant refuses to suck the breast. In the meantime the gland becomes more and more distended, and the nipple deeply buried, until at last suckling is impracticable. Probably none of these increasing troubles have been stated to the attendant surgeon; and, when he is consulted, he finds the breast to be in the state presently to be described. Either the orifice of a duct is obstructed by epithelium, or a superficial ulceration exists around it. The entrance of pyogenic bacteria through such a lesion near or upon the nipple is the immediate cause of the mammary abscess.

Inflammation of the breast is most frequent in primiparæ, and within the first month after parturition.

Inflammation does not often occur at the time for weaning the infant, nor in the passive state of the breast. Small chronic abscesses with thickened walls

are, however, occasionally found in middle life, and the accompanying enlargement of the axillary glands and slight retraction of the nipple may lead to such cases being mistaken for cancer.

SYMPTOMS.—First, hardness is felt, ‘a knot,’ in some part of the breast; this enlarges, and may attain to considerable dimensions before causing pain or even uneasiness. Next, pain is felt during suckling; this increases each time the infant sucks. The integuments then become pink, and afterwards red, tense, and shining; more or less of the breast feeling very inelastic, firm, prominent, and heavy. Pain is now often very severe, and great constitutional disturbance is excited. In the centre of the redness the skin becomes of a purplish tint; around this it is oedematous; and with the finger, at the centre of the purple zone, a slight depression and softening spot can be detected. An abscess now exists, and fluctuation is more or less marked in proportion to the quantity of pus. At the purple centre the cuticle has probably by this time separated from the cutis; and a vesicle containing serum, either yellow, or slightly tinged with blood, indicates that ulceration of the cutis is proceeding, and that the pus will soon escape. The above is a brief description of the objective signs noticeable in untreated cases of local inflammation advancing to and terminating in supuration and abscess. It is not possible to state the exact period of time required for the accomplishment of these definite changes, as this varies with many local and constitutional circumstances.

VARIETIES.—When supuration has taken place, the exact site of the abscess should be carefully ascertained. It may be situated over the body of the gland, within it, or beneath it.

When *overlying* or superficial to the body of the breast, the course of the disease is rapid. In these cases the constitutional disturbance is usually trifling.

Both the local and constitutional symptoms are much more severe when inflammation affects the *body* of the gland, and pus collects between its lobes. The progress of the disease is tedious; the pointing of the pus is slow, and the exact spot at which it may reach the surface is for a long time doubtful. In the majority of cases it makes its way between the ducts, and reaches the surface near the areola or within its area; usually to the sternal side of the nipple, where the gland-tissue is thinnest.

When the abscess forms *beneath* the breast the local appearances are quite characteristic. The gland itself seems little involved, but it is pushed prominently forwards and seems to rest upon a cushion of fluid. To the touch the elasticity of the swelling is very striking, and, without producing additional pain, a slight bulging of the walls of the abscess may sometimes be produced at the periphery of the gland when, with the palm of the hand and outspread fingers, compression is made from the front backwards against the thorax. The patient should be recumbent. The pus in these cases often points somewhere around the borders of the body of the gland.

TREATMENT.—Great attention should be given to the nipples of primipare. Prophylactic measures should be instituted when there is reason to fear that a defective development of the nipple will interfere with the free flow of the milk, and it may occasionally be necessary to forbid suckling on account of the mechanical impediments and the pain caused by the attempt. If the nipple be imperfect, precautions should be taken to prevent the gland itself from

becoming congested, and if the infant cannot draw the milk sufficiently, some mechanical means should be employed to effect this object. The nipple itself should be examined. If its end be more than usually coated with secretion, or the openings of the ducts seem to be obstructed with an excess of epithelium, attempts may be made to remove it. If abrasions, ulcers, ‘cracks,’ or ‘chaps’ are visible between the rugæ, a soothing application, or a weak solution of carbolic acid, should be used. Ablution with warm boiled water, or the contact of a little moist boric lint, covered with gutta-percha tissue, is often sufficient; or, if there be much secretion from the glands on the nipple, after cleansing its surface, some dry powder is beneficial, such as carbonate of magnesium, oxide of zinc, or starch powder.

When actual congestion of the gland-tissue exists, mechanical means should be used to reduce it. Supporting the gland with strips of plaster and a bandage is sometimes very useful. When inflammation is excited the infant must be weaned, and the milk drawn off by the breast-pump from the opposite mamma. The patient must be purged and placed on a dry diet, while iodides and belladonna must be administered internally. The application of glycerin of belladonna and a suitable support of the breast are also of great service, and gentle massage by the hand of the nurse, directed from the nipple towards the periphery of the gland, is often beneficial.

As soon as the presence of pus is ascertained, it should be evacuated by means of a short incision radiating from the nipple. This must be kept open by as large a drainage-tube as the incision will admit, and the strictest antiseptic treatment should be employed. The omission of the latter is very likely to lead to burrowing of pus and the development of troublesome sinuses.

The constitutional powers of the patient must be well supported, and the general health maintained by every possible means.

The *sequelæ* of supuration in an organ composed of so much connective tissue, and endowed with its peculiar function, sometimes cause great trouble; they are, however, much less frequently met with now than before the introduction of the antiseptic treatment. They are protracted induration, sinuses, and fistulæ, through which last the milk persistently escapes. Induration of the whole or part of the breast subsides when lactation ceases, and the organ in due time resumes its healthy state. Sinuses and fistulæ may require incisions, but the ordinary methods for their cure should be adopted before having recourse to a treatment often involving much subsequent deformity.

Any considerable fullness of the breast occurring when the process of weaning the infant is begun may be relieved by mechanically drawing the milk in just sufficient quantity to diminish the fullness.

In the chronic abscess of middle life an exploratory incision, which often furnishes the only certain guide in diagnosis, constitutes the most satisfactory treatment.

Tubercular Abscess of Breast.—This affection is rare, but very important. The abscesses are generally chronic or ‘cold’ abscess, the skin over them being blue, and the pus they contain thin and watery. The *Bacillus tuberculosis* may be found in the discharge. The abscesses are frequently multiple, and the breast-tissue may be extensively destroyed. The axillary glands are enlarged and caseous. The surgical treatment lies in either

opening and erosion of the cavities and glands, or removal of the entire disease. The climatic and other general treatment for tubercular maladies should be thoroughly carried out.

Galactocoele.—An accumulation of milk, to which this term is given, may result from the bursting or the obstruction of a lactiferous tube, and form a tumour in the connective tissue of the breast. The swelling always appears first during lactation. It may vary in size from time to time; sometimes enlarging rapidly as suckling goes on. Two varieties are met with. In the one form there is a single swelling near the nipple, quite superficial, and quickly recognisable by its objective signs. In the other there may be several swellings distinguishable in the substance of the gland, as well as on its surface, all of comparatively small size, very firm and globular. In the same gland they vary very much in size and in the degree of resistance they offer to manipulation. The discrimination between these tumours and others in the breast is easy, if it can be ascertained with exactness that the swelling appeared somewhat suddenly during suckling, and that its size varied with that function.

In cases of long standing, the contents of the cyst become solid in proportion to the quantity of the fluid constituents of the milk absorbed, and the cyst-wall itself is very often rigid and even may become calcareous. Such cases have been confounded with cancer.

TREATMENT.—The treatment of the chronic cases consists in dissecting out the cyst.

Chronic lobular mastitis.—When the tissues of a mature but perfectly passive gland are examined with the microscope, the caecal terminations of the ducts are found to be small, and little else than fibrous tissue is seen. Here and there, at their blind ends, spaces may be detected containing minute aggregations of epithelium. But when, under some sympathetic excitement, with derangement of the functions of the pelvic generative organs, the secreting cells of the gland become active and are distended with epithelium, they induce more or less enlargement of the breast. This condition of things is called *chronic lobular mastitis*, and should perhaps more properly be included among the inflammatory diseases of the organ. But of such affections there is this important fact to be noticed. The whole breast need not be necessarily involved. On the contrary, one lobe only may be excited, and when this occurs the existence of a tumour is declared. When, after excision, such enlarged lobes are carefully examined with the microscope, normal gland-tissue is seen, the caecal ends of the ducts are readily recognised, and their immediate association with the excretory channels may be observed. The former are gorged with epithelium; and true gland-tissue, less its peculiar secretion, has been developed.

SYMPTOMS.—Associated with this state of the issues of the breast, the patient complains of pain, both local and spreading over a very wide area. To express as briefly as possible the superficial regions affected and over which pain is felt, the reader must be reminded of the distribution of the descending cutaneous branches of the cervical plexus, and of the lateral and anterior cutaneous branches of the second, third, fourth, and fifth intercostal nerves. From these, special filaments are distributed to the breast; and to the site of exit of one or more of them at the intercostal

foramina, the source of the pain is referred by the patient. The skin of the neck, shoulder, side of thorax, and inside of arm receives filaments from the same source. Hence an explanation of the widely diffused pain.

It is of the first importance to discriminate between this state of the gland-tissue and substantial new-growths, especially because the latter cannot be removed by natural processes, while the former most probably will be. The objective signs are the following: to the touch the implicated gland-tissue is nodular, and mingled with the body of the organ. If the whole breast be large and relaxed, the tips of the fingers may be insinuated between the borders of the indurated lobe and the lobes not affected. If the entire body of the gland be morbidly firm, it feels like a disc-shaped mass lying on the thorax, under the borders of which the fingers can be pressed. Occasionally, at one or more spots along the periphery of the gland, irregular nodules are perceptible, projecting into the connective tissue around them. When one lobe is affected, the shape of the induration may correspond with that of a lobe—i.e. broad at the periphery and gradually narrowing towards the areola. Pain is of assistance in forming a diagnosis in these cases; but the source and course of the pain must be carefully traced. Generally manipulation of the induration produces increased pain; occasionally a mere touch is intolerable. Light pressure should be made over the points of exit of both the anterior and lateral branches of the intercostal nerves, when the pain excited thereby will correspond with the nerve-filaments of the affected lobe. Pressure along the upper dorsal spinous processes usually excites pain also. The morbid affections above described occur in single women, married but sterile females, and young widows, at any age between twenty and forty years. More or less disturbance of the catamenia co-exists, either in relation to the frequency or quantity of the discharge. The patient complains of languor and inability for bodily or mental exertion; and she is desponding and often alarmed at the consequences suggested by sympathising friends. She is irritable, emotional, restless at night, and loses appetite for food, as well as all desire for social enjoyments.

DIAGNOSIS.—An exact diagnosis may be made if the manipulator examines the organ methodically. He should, first, gently grasp the induration between the thumb and fingers, when it will be distinctly appreciable. Afterwards, placing the palmar surface of the fingers over the surface of the breast and gently pressing backwards against the thorax, the induration will not be detected. Should there still remain any doubt on the subject, the patient should be placed on her opposite side on a sofa, and in this posture, if there exists any substantial mass, the integument is usually elevated by it.

As a general rule it may be stated that if a distinct lump is felt by the fingers of the surgeon when laid flat upon the mamma this is more than mere chronic mastitis. Such a lump or prominence will be probably a cyst or an early cancerous nodule.

TREATMENT.—The treatment of these cases consists in careful attention to the general health. Local soothing applications are usually futile, and, except in cases of extreme pain, are unadvisable; but strapping with belladonna plaster may give

their remarkable mobility, slight lobulation of surface, and firmness, coupled with the youth of the patient, are sufficient indications of the harmlessness of their nature. Usually they occur singly and in one breast: they may be multiple and in both breasts. The only means by which they can be removed is excision. In young persons, however large the tumour, its removal should be always attempted without cutting away any portion of the normal breast. In most cases this can be done, especially if the patient be youthful and the growth of medium size, even should it be developed in the body of the gland and extend through it to the pectoral muscle. After thirty-five years of age it is expedient to remove the breast as well; for these tumours are then sometimes associated with cancerous growth. A section shows a solid, uniform surface, divided into lobes and lobules by fibrous septa, sometimes slightly broken up by fissures or clefts in which there appears a little clear tenacious fluid. The section is often very succulent, at other times only moist; its hue may be greyish, yellow, or almost white. Its vascularity is scarcely perceptible. The prognosis in these cases is invariably favourable.

Carcinoma and Sarcoma.—The usual period for the appearance of cancer in the female breast is between the ages of 35 and 55, but instances occur in younger and also in older women. Blows, inflammation, old abscesses, and retracted nipples, are potent predisposing causes. Various kinds of carcinomata are described, but the spheroidal-celled growth is the common one. This may undergo colloid or fatty change, and may also be mixed with blood-cysts. Thus the terms 'colloid cancer' and 'hæmorrhagic cancer' have originated. A peculiar kind of cancer has also been described which appears to originate in papillary growths in the ducts. The epithelium is columnar in shape, and the tumour is soft and honeycombed with cysts of various sizes, containing coloured fluid (*duct-cancer*). The commencement of cancer of the breast is a peculiar affection of the skin round the nipple known as 'Paget's disease' or 'malignant dermatitis of the nipple' must not be overlooked. See NIPPLE, Diseases of.

SYMPTOMS.—The clinical history of cancer of the breast is of surpassing importance; in its early beginning this serious malady is too often ignored or concealed, and the extreme necessity of detecting and treating it in its earliest stage is still often overlooked. The affection may be noted accidentally as a small lump or tumour, or a mere hardening not larger than a pea or bean in the breast-substance. Pain is usually absent.

Rarely, the whole organ is simultaneously infiltrated, but most frequently one lobe only is affected. The infiltration is often central in the body of the gland, especially when the organ is atrophied, and the reverse occurs when the extreme edge of a lobe is affected at its periphery. The infiltration may steadily increase until the whole breast forms a rigid, solid mass; but most frequently the larger part of the organ remains unaffected. The disease gives rise by its contraction to much deformity of the region, to dimpling, corrugation, and irregularities of the otherwise rotund integumental surface. The nipple, just in proportion to the effect of the growth upon the ducts, becomes retracted or drawn towards the tumour. Sooner or later the integument over the growth becomes adherent to it,

infiltrated, and red, and advances towards ulceration. An ulcer now forms, the edges of which are everted, ragged, and attached to the growth beneath. A hole extending into the tumour becomes deeper and deeper; ichorous discharges, more or less profuse, continue without much pain; and the patient becomes at last worn out by fever and septic infection, or succumbs to the ravages of a cancerous growth in a vital organ.

The rate of progress of this disease varies remarkably. In some individuals the disease does not destroy life. In general terms its progress may be said to vary directly with the age and vigour of the individual. In young women, especially when pregnant or during lactation, cancer advances with such rapidity that no operative measures seem of much avail. In old and withered women, on the other hand, the disease may remain quiescent for years, or may actually retrogress (*atrophic cancer*). It is upon these natural vagaries of the disease that quacks and impostors flourish; for any remedy taken in a case of atrophic or withering cancer is sure to receive the credit for what is really the natural course of the malady. The diagnosis of cancer of the breast is usually obvious; on the other hand it may be most difficult even for experts.

TREATMENT.—Nothing but operation is of any value. All vaunted remedies, such as electricity and patent preparations, do not bear the investigation of scientific and unprejudiced observers. Removal of the ovaries and the administration of thyroid extract have seemed to check the growth, and especially the pain of inoperable recurrent cancer. For other cases this treatment is more severe and not so certainly beneficial as the ordinary operation. The results of the modern operation for cancer enable the surgeon to give a far more hopeful view of the future of the patients than was formerly possible. Cases of prolongation of life for periods of from three to six years are fairly common, and even in cases where the disease returns the avoidance of a huge fungating mass upon the chest-wall is a boon which can hardly be over-estimated. The two essentials to success are early and free removal. In cases which have been neglected and concealed, and in which glands are extensively involved, respite is generally all that can be hoped for.

The modern operation consists in not only removing the breast and all its outlying lobules, but also the fascia over the pectoral muscle, and the muscle itself, should the growth be at all extensive. The glands and connective tissue in the axilla are in *all* cases to be carefully dissected out. Should the pectoral muscle not be cut away, it may be divided, and this will give very free access to the axilla and permit the removal of all axillary tissue. The cut muscle can be reunited with catgut or kangaroo-tendon. Great care must also be exercised in the removal of all integument involved, and, should the parts not come together, the method of Thiersch, or some other form of skin-grafting, must be employed (see SKIN-GRAFTING). If strict asepsis be ensured these extreme operations are not dangerous. They should, however, only be performed by experienced operators who will not hesitate to dissect out the fat and axillary glands from the nerve-trunks and great vessels. Imperfect removal of the disease is followed by rapid recurrence, and the operation falls into

undeserved disrepute owing to the imperfect and faulty action of its performer.

Sarcoma.—Under this heading, as well as that formerly employed of 'fibroplastic tumour,' we include a group of new-growths composed of sarcoma-tissue, with round, spindle, or mixed cells, in which are interspersed somewhat modified acini and ducts of the gland.

The microscopical characters of the tumours are very varied and peculiar, and in some instances closely resemble the remarkable tumours (myeloma) present in connection with the medullary tissue of bone.

Sarcomatous tumours of the breast are found in young or middle-aged women. They have been seen in girls of sixteen and twenty. The physical signs are those of a round or oval tumour, which increases progressively or grows by fits and starts. The veins over the tumour are enlarged, and the integument is dusky and sometimes the seat of ecchymoses. The rate of growth and the associated symptoms correspond with the degree of malignancy of the tumour. Some of the worst kinds are soft and jelly-like, and are often confounded with cysts or abscess. Very free removal of the whole breast and of the axillary lymphatics should be adopted in these cases. They are apt to recur *in loco* after removal, and when of rapid growth in pregnant and lactating women the prognosis is usually of a gloomy nature. In the more slowly growing and encapsuled forms, the prospect for the patient is good.

III. Diseases of the Male Breast.—The male has sometimes a well-developed mammary gland, and the part is subject to the same diseases as in the female. Thus cancerous tumours, fibroadenomata, and cysts may all occur in the male breast. Their symptoms and clinical history are identical with what is found in the female. All these affections are exceedingly rare. The simple enlargement of the organ is harmless, and should not be interfered with. At the age of puberty the mammary region often becomes painful, owing in part to the pressure of the dress upon the mamilla and the rudimentary organ. Inflammation followed by suppuration has been observed at this time.

IV. Diseases of the Nipple.—A defective formation of the nipple is of grave importance, and when it exists measures should be adopted to assist its elongation. This is to be done by using an exhausting-glass, such as those employed to empty the gland of milk.

Inflammation and its effects produce much suffering, and at the period of suckling frequently excite deep-seated mischief. The small ulcers, called 'cracks' or 'chaps,' which form between the rugæ on the apex and sides of the nipple, may be cured by a dressing of boric lint, or by powdering the part with carbonate of magnesium or oxide of zinc or by bathing with a weak solution of carbolic acid.

Eczema round the nipple is common, and must not be confounded with malignant dermatitis. See NIPPLE, Diseases of.

Pendulous cutaneous growths occur on the nipple and should be excised.

Cystic follicular tumours are sometimes seen within the zone of the areola.

JOHN BIRKETT.

A. MARMADUKE SHEILD.

BREATH, The.—The expired air, or what is familiarly termed *the breath*, is important both from an ætiological and a clinical point of view, and the object of the present article is to present a brief summary of the main facts relating to this subject, from a clinical point of view.

a. The breath has been made use of to distinguish between *real* and *apparent death*. See DEATH, Signs of.

b. The *temperature* of the expired air may be altered. In some conditions, as in the collapse-stage of cholera, it becomes cold, and this may be perceptible to the hand, or it may be visible in consequence of the moisture in the expired air being condensed, even when the surrounding atmosphere is warm. On the other hand, the temperature of the breath may be raised, as in febrile diseases.

c. *Chemical examination* of the breath may prove of service. In certain affections, as during an attack of asthma, or in cases of extensive bronchitis, the amount of carbonic acid in the expired air is more or less increased; in others, such as in the collapse-stage of cholera, this constituent may be very deficient. Again, chemical examination of the breath may reveal the presence of a poison in the system, introduced from without, for example, hydrocyanic acid. It has also been employed to show the existence of deleterious products generated within the body, especially in cases of renal disease.

d. *Microscopical examination* of the expired air has been attempted, but at present no results of practical value have been obtained.

e. The *odour* of the breath is the most important character demanding attention from a practical point of view. At the outset it must be observed that in some individuals the breath seems to have naturally a disagreeable odour, which cannot be referred to any particular cause. This is sometimes only temporary, and in females may only be noticed at the menstrual periods. It must be borne in mind that the breath is frequently unpleasant, either temporarily or constantly, owing to indulgence in certain articles of food, or in certain habits, such as smoking or chewing tobacco.

(i.) The odour of the expired air may aid in the recognition of a poison inhaled or swallowed. The smell of prussic acid or laudanum, for instance, may be revealed when either of these is present in the stomach. In cases of acute alcoholic poisoning, the odour of the alcohol or of its products is at once apparent; and in persons who are found in a state of unconsciousness, the smell of the breath is made use of as one of the diagnostic signs of drunkenness, if it be previously ascertained that no alcohol has been administered as a restorative. It is in the chronic forms of alcoholism that the breath gives the most valuable information. In marked cases of chronic alcoholism it has a quite characteristic odour; moreover, this peculiar odour often enables us to detect dram-drinkers, and to explain the symptoms of which they so frequently complain; as well as to detect intemperance in candidates for life-insurance. Again, the breath may reveal the presence of certain metallic poisons in the system, of which mercury is the most important example, but lead may also affect its odour. In cases of diabetes mellitus, and especially diabetic coma, the breath may have a sweetish, fragrant, or ethereal odour, attributed to acetone.

(ii.) The breath has peculiarities of odour in many different diseases. That which is associated

with the febrile condition is well known. In various disorders of the digestive organs the breath is often very offensive, but it is not practicable to refer any particular odour to any particular disease of any of these organs; it may, however, be affirmed that an unpleasant smell is frequently associated with habitual constipation. In cases of stercoraceous vomiting the breath may have a distinctly faecal odour. In this relation it may be mentioned that in some cases of phthisis the writer has noticed a sickly smell of the breath which is quite characteristic, and which seems to depend upon the state of the stomach. In cases of cerebral disease, also, the breath often becomes exceedingly offensive, on account of the condition of the alimentary canal. Local morbid conditions about the mouth, throat, or nasal cavities constitute a most important class of affections which influence the odour of the breath; in many cases it becomes extremely foul, and may be quite peculiar in its characters. Among these conditions should be specially mentioned want of cleanliness of the mouth and teeth; decayed teeth; diseased bone in the mouth or nose; ulceration or gangrene about the mouth, especially cancrum oris, and gangrenous ulceration along the gums; suppuration, ulceration, or gangrene in the throat, either of local origin, or associated with syphilis, scarlatina, diphtheria or other general diseases; ulceration of the nasal mucous membrane, and chronic *oæna*; and malignant disease. The smell of the breath is of value in drawing attention to some of these conditions, for, in the occasional absence of other symptoms, the patient may be quite unconscious that there is anything wrong. Again, certain conditions of the respiratory organs are liable to affect the odour of the expired air, and may render it unbearably foetid. Among these may be mentioned sloughing ulceration about the larynx, pulmonary gangrene in any form, and the decomposition of retained morbid products in dilated bronchial tubes or in certain cavities. Here, again, the smell of the expired air may reveal what otherwise is liable to be overlooked, and especially when the patient coughs, and so expels some of the reserved air. Lastly, the breath may have a peculiar odour in some special diseases, such as pyæmia and its allies; and after the administration of certain drugs, such as paraldehyde.

TREATMENT.—It is only intended here to offer a few remarks as to the treatment of *foulness of breath*. The first great indication is, of course, to seek out the cause of this symptom, and to endeavour to remove it. The habits should be duly regulated; the mouth and teeth properly cleansed; the alimentary canal maintained in good order; and any special affection requiring treatment attended to. When unpleasant breath depends on the stomach, it may often be improved by taking charcoal, at the same time remedies being employed suitable for the particular affection present, and calculated to promote the functions of the alimentary canal, the bowels being also kept freely open. When the bad smell depends on local causes, it may be diminished by the use of antiseptic mouth-washes, gargles, sprays, or nasal douches of Condy's fluid, peroxide of hydrogen, carbolic acid, or creasote. Antiseptic inhalations or injections are indicated in fœtor from the air-tubes. See BRONCHI, Diseases of.

BRIGHT'S DISEASE.—SYNON.: Fr. *Maladie de Bright*; Ger. *Die Bright'sche Krankheit*.

Bright's Disease may be defined as an acute or chronic inflammatory affection of the cortex of the kidneys, often accompanied by secondary lesions in other organs of the body, especially the heart and blood-vessels.

A great number of morbid processes have been included under the name of Bright's disease by different writers, but at the present day the term is becoming limited to certain acute and chronic inflammatory affections. All forms of nephritis are, however, not to be included under the name of Bright's disease, although in many respects the changes produced in the kidney during acute nephritis are essentially similar to those seen in the early stages of acute Bright's disease. The distinction between nephritis and acute Bright's disease depends essentially on the fact that the lesion in the latter tends to be progressive, and, further, that general effects, such as dropsy, occur which are unknown in cases of simple nephritis. The distinction between a typical case of acute nephritis and a typical case of acute Bright's disease is thus easy, but many anomalous forms are seen where this distinction breaks down. Acute Bright's disease is sometimes seen unaccompanied by dropsy during the acute stage, but where the subsequent history of the case, or maybe the death of the patient, shows clearly that the disease was progressive and accompanied by the other phenomena such as uræmia, secondary inflammations, and cardio-vascular changes characteristic of Bright's disease. The difficulty of differentiating between nephritis on the one hand and Bright's disease on the other is so great that some writers consider Bright's disease and nephritis synonymous terms. One objection to this view is that some forms of Bright's disease are of such a slow and insidious onset that they do not present an inflammatory character at any period of their course. A further difficulty is introduced by the fact that the ætiology of many forms of nephritis and that of Bright's disease are essentially similar. The poison of scarlet fever during the height of the malady may produce a condition of slight nephritis characterised clinically merely by the presence of albuminuria. On the other hand during the subsidence of scarlet fever typical Bright's disease may be produced characterised by copious albuminuria, onset of dropsy, and all the toxic symptoms associated with the disease. Either two forms of nephritis must be recognised, one transitory and partial in its distribution, the other more general and tending to be progressive in its course; or else the term *nephritis* must be limited to the former, and acute Bright's disease to the latter. Some writers have ventured to describe acute Bright's disease under the form of acute nephritis, restricting the term of true Bright's disease to the chronic forms of the disease. Bright's disease is separated with difficulty not only from nephritis but also from certain chronic degenerative processes of the kidney. Many writers have included the waxy kidney under the term of Bright's disease, and Bright did this himself. This confusion arose partly from the fact that in many forms of true Bright's disease amyloid degeneration of portions of the kidney is not uncommon. Further, the amyloid kidney presents great resemblances clinically to

some forms of chronic Bright's disease, and there is a superficial resemblance in their morbid anatomy. Lastly, both the amyloid kidney and Bright's disease may arise as complications of one and the same malady, e.g. phthisis, syphilis. The amyloid kidney, however, has only a superficial resemblance to Bright's disease and should be sharply separated from it, if for no other reason, because frequently its treatment is quite different from that of Bright's disease. In many forms of Bright's disease there is a considerable overgrowth of the fibrous tissue of the kidney, and there are also marked changes in the heart and blood-vessels, and in this way there is some resemblance brought about between some forms of Bright's disease and what is ordinarily spoken of as the granular kidney. The true granular kidney, however, has no real relationship with Bright's disease and is an independent affection.

The term 'Bright's disease' in this article will therefore not include certain forms of nephritis nor the amyloid kidney nor the granular kidney.

Varieties.—Bright's disease, even thus limited, presents many varieties which have been classified differently by different writers. All writers are agreed that an acute form and a chronic form may be recognised. In the acute form all the constituent elements of the kidney suffer, but in different cases to different extents. In some forms of acute Bright's disease the main effects of the morbid process are seen in the glomeruli, in others the most marked results are the degenerative changes occurring in the epithelium of the tubules. In others perhaps the most marked effects of the inflammatory changes are seen in the interstitial tissue. In all forms, however, these three elements of the kidney are always affected. Not only are the different elements of the kidney affected to different extents in different cases of acute Bright's disease, but even in one and the same case the lesion is developed to varying extents in different portions of the organ. It is one of the most characteristic features of Bright's disease that although the morbid change affects both kidneys the severity of the effects produced varies considerably in different parts of the organs.

Chronic Bright's disease presents many varieties both from the point of view of the clinician and that of the morbid anatomist, and it is customary to recognise two fundamental varieties: (1) the so-called large white kidney, and (2) the contracted or atrophic white kidney sometimes called granular or cirrhotic, but the latter terms are better restricted to the description of the true granular kidney, which is not here included under Bright's disease. Not only do these two forms of chronic Bright's disease present marked anatomical differences, but there are also differences in their clinical course, and they may probably be recognised as real varieties. For the purposes of this article, therefore, *three* forms of Bright's disease will be described: acute Bright's disease and two varieties of chronic Bright's disease.

ÆTIOLOGY.—Bright's disease both in its acute and chronic forms is probably dependent in the great majority of instances on the action of some toxic agent present in the blood-stream, on the renal structures, and more especially on the glomeruli and the epithelium of the cortex. The toxic agent producing these ill effects may be one produced in the body by the action of microbic processes, as is the case in all probability in the acute infective diseases. The toxic agent, however, in a very large number of instances is one that is ingested, as in the case of

alcohol or of mineral poisons, such as lead and mercury. It is also possible that toxic substances having a deleterious action on the kidney may be formed in the body as a result of deranged processes of metabolism. Although toxic agents will account for the great majority of cases of acute and chronic Bright's disease, it is held by many clinicians that these maladies may arise in other ways, as for instance as a result of exposure to cold. The rôle played by cold in the causation of morbid processes is not now held to be so direct as it formerly was. In many instances where cold is reputed to act as the direct exciting cause it really only produces its effects indirectly. Thus many diseases imputed to the action of cold are really dependent on microbic infection, which is more able to produce its effects owing to the lowered resistance produced by the cold. In the case of renal diseases instances are undoubtedly seen where the malady has apparently arisen as the result of exposure to cold, and especially to damp cold. Thus the disease is not uncommonly seen in workmen who work in hot shops and pass out into the open air scantily clothed; also in boiler-cleaners, engineers, and others who experience great vicissitudes of temperature, but in many of these cases it is difficult to exclude the action of other and toxic agents, as, for instance, alcohol, lead, &c. It has also been thought that mechanical causes, such as the pressure of the pregnant uterus on the renal veins, might lead to Bright's disease, but here also it is probable that the association, which is a real one, is dependent rather on the action of toxic substances than on the mere mechanical effects of pressure. The action of cold in the production of renal disease has been thought to be probably owing to the intimate relationship existing between the action of the skin and that of the kidneys, and it has frequently been taught that exposure of the skin to cold, causing contraction of the cutaneous vessels, produced reflexly an engorgement of the kidney. There is, however, no experimental evidence justifying this hypothesis, and it has been suggested that if cold is really an important factor in the production of renal disease, the effects produced are not dependent on any congestion of the renal vessels brought about by the nervous system, but rather that the arrest of the cutaneous secretion leads to the retention of toxic material in the blood-stream, causing an injurious action on the renal structures. Although perhaps it cannot be denied that congestion of the kidney may be brought about through the nervous system, yet at the present day the only definite manner in which nephritis can be produced is by the action of toxic agents.

Renal poisons may be divided into three groups. The first consists of bodies like cantharides or like the virus of scarlet fever, which produce almost similar results of which the most marked is glomerulo-nephritis. A second group of renal poisons consists of the metallic salts, the oxides of the heavy metals, and such bodies as chromic acid, all of which produce a coagulation-necrosis of the cells of the convoluted tubules. A third group of renal poisons consists of certain animal and vegetable toxic substances, such as abrine, ricine, serpent-venom, and the blood of certain fish, e.g. the eel. These complex bodies produce a degeneration of the epithelial cells of the kidney, which, however, is not so complete as the coagulation-process produced by the action of the heavy metals. Recently it has been asserted that renal lesions are produced by a number of

bodies belonging to the group of substituted ammonias, and more especially by such bodies as vinylamine, cadaverine, and putrescine. There is thus a wide range of toxic substances capable of producing a great variety of renal lesions.

Bright's disease, especially in its acute form, is most frequently the sequela of an acute specific disease, and more especially of scarlet fever. It is, however, also seen after other acute diseases, such as diphtheria, erysipelas, pneumonia, measles, rheumatism, pyæmia, and typhoid fever. It is interesting, as remarked above, that most of these diseases, cause during their height a febrile albuminuria dependent on the existence of transitory nephritis. Acute Bright's disease, however, arises at a later period of the progress of the malady when convalescence is approaching. Pregnancy may also be recognised as a cause; and Bright's disease sometimes arises in the course of certain chronic diseases, such as heart-disease, gout, and diabetes. Acute Bright's disease is also seen as a complication of burns, and in certain skin-diseases, especially pityriasis and eczema, and it is possible that in this latter instance the lesion is dependent on the formation of toxic bodies in the skin and their subsequent absorption and excretion by the kidneys. Alcohol, cantharides, turpentine, mineral acids, and carbolic acid may all cause acute Bright's disease. Cold is also held by many observers to be a direct and exciting cause of some of the most acute forms of Bright's disease. Toxic agents are therefore most frequently the direct and exciting cause of acute Bright's disease, but there are some predisposing causes, such as occupation and indulgence in alcohol. Engineers, boiler-cleaners, glaziers, potters, painters, and barmen are all especially liable to suffer from this disease. Bright's disease is more common in men than in women in the proportion of three to two, and is most common between the ages of three and forty. In some instances hereditary influences seem to play a part; this is more especially the case in the chronic forms of the disease. Passive congestion of the kidney from heart-disease is also held to be a powerful predisposing cause.

The ætiology of chronic Bright's disease is similar to that of the acute disease. The disease is frequently the result of gout and of the action of such poisons as alcohol and lead; it also supervenes in certain occupations necessitating exposure to cold. Chronic Bright's disease is not produced, however, by the action of the poisons of the specific fevers directly; whenever it results from scarlet fever or other acute specific, it is really the sequel of an attack of acute Bright's disease produced in these diseases. Chronic Bright's disease may therefore arise as a sequel of the acute form, or it may be chronic from the commencement; large numbers of cases of chronic Bright's disease have never been preceded by any attack of the acute disorder. Sometimes chronic Bright's disease supervenes directly as a sequel of acute Bright's disease, in other cases the acute stage of the malady subsides and health is regained, and subsequently, as a result perhaps of exposure to cold or from indiscretions in diet, a further attack of acute or subacute nephritis is induced, and the chronic disease dates from this second or maybe from a third attack.

The relationship of the two forms of chronic Bright's disease, the large white kidney and the contracted white kidney, is somewhat doubtful. It is possible that in some cases the contracted form of

the disease is a terminal stage of the other, the diminution in the size of the organ being dependent largely on atrophy of the renal elements, together with great overgrowth of connective tissue. Frequently, however, the contracted white kidney is seen in the *post-mortem* room without there being any previous history suggesting the occurrence of the large white kidney. Many patients dying with a contracted kidney have never suffered from dropsy, which is such a characteristic feature of the large white kidney. In some instances where the contracted white kidney is well marked, a history of an acute specific fever followed by acute nephritis may be obtained, and it would seem as if in these cases this form of Bright's disease was the terminal lesion and in some way related to the occurrence of acute nephritis, and more especially of scarlatinal and glomerulo-nephritis. It is not uncommon, however, for the contracted white kidney to occur not only without the history of any previous renal illness, but also without there being any history of any acute disease; therefore it would seem that the contracted white kidney may exist as an independent disease, and that all cases of it are not necessarily preceded either by acute nephritis or by the large white kidney.

MORBID ANATOMY.—*Acute Bright's disease.* In the acute stage the kidney is considerably enlarged, weighing seven or more ounces, the capsule strips off readily, and the organ is gorged with blood, dark-red in colour, the congestion being most marked in the stellate veins and in the pyramids. The colour of the section and the colour of the surface depend largely on the duration of the disease; in the early stages they are of a deep-red colour, but after the lapse of a week to ten days the surface is mottled or marbled, owing to the presence of yellowish or greyish-yellow areas, caused by degeneration of the epithelium; if the duration of the disease has been as long as six weeks, both the external surface and the section show the cortex of a more or less uniform, peculiar yellowish-grey colour dotted with spots and streaks of congestion. The pyramids are usually intensely congested, and the glomeruli can sometimes be seen as bright-red points. Microscopically the glomerular chamber often contains blood-corpuscles and exudation, and the vessels of the tuft have frequently undergone hyaline degeneration. The vessels generally are gorged, and this is especially marked in the straight vessels passing up in the medulla. There may be a considerable amount of leucocytic infiltration of the interstitial tissue, and this is often especially well marked in the connective tissue round the glomerulus. The epithelium of the glomerular chamber may undergo considerable proliferation, forming a crescentic mass between the basement membrane and the capillary tuft. The cells of the convoluted tubules are frequently shed, occupying the lumen of the tubules, which are dilated to varying extents. Where the epithelium remains the cells have undergone degeneration, cloudy swelling being marked, and in other instances the cells have lost their striated border and have assumed a glass-like or hyaline appearance. The lumen of the tubules is occupied by blood-corpuscles, disintegrated renal cells and casts, the casts consist in some cases of coagulated blood-plasma, forming hyaline and granular casts, or of aggregations of renal cells, which have undergone degeneration. The changes in the medulla are similar, but not so well marked. Although in

acute Bright's disease the changes in the cortex of the kidney are widespread and cause considerable apparent increase in the amount of cortex, yet these changes are rarely evenly or uniformly distributed, and this statement really applies to all forms of Bright's disease. Areas are seen where the glomerular and tubular changes are far more marked than in adjacent areas, and in some parts the glomeruli and renal tubules may present appearances but little different from those of health.

Chronic Bright's disease.—In the so-called large white kidney, the organ, as the name implies, is enlarged and perhaps double its usual size, but the anatomical changes present are essentially similar to those seen where the organ is but little increased in size. The capsule strips off readily, leaving a smooth, opaque, yellowish-white surface, on which the stellate veins are conspicuous. The colour of the surface may be somewhat mottled; the colour depends largely on the degree of congestion. On section, the cortex is relatively increased and presents the same appearances as those seen on the surface. The medulla is usually deeply congested and stands in marked contrast to the cortex. The pyramids seem unduly separated owing to the increase in the amount of cortical substance. The glomeruli, the tubules, and the interstitial tissue all show changes. In the large white kidney the glomeruli are usually larger than normal and the capsule is thickened to a moderate extent, there is some cellular infiltration of the glomerular tuft, the epithelial lining of the chamber has undergone marked proliferation, and the walls of the capillaries frequently show signs of hyaline degeneration. The tubules of the cortex are in places dilated, in others collapsed, in others presenting over small areas perhaps fairly normal characters. In the dilated tubules the epithelium may be shed, but where it remains it has commonly undergone hyaline, and in some places fatty, degeneration. The tubules generally contain casts. The interstitial tissue shows usually considerable overgrowth of fibrous tissue, and there is more or less abundant small-celled infiltration. The vessels are not commonly unduly prominent on section, but microscopically they frequently show thickening of the sub-endothelial layer of the intima to a moderate extent.

In the other form of chronic Bright's disease, where the kidneys are white and contracted, the capsule is usually thickened and on stripping leaves a granular surface, the granulations of which are frequently large and exceedingly well marked. The cortex is notably diminished in thickness, measuring frequently not more than one-eighth or one-sixteenth of an inch. The capsule although thickened is not invariably unduly adherent. Microscopically in this form of the disease there is a great increase of fibrous tissue; the glomerular capsules are frequently thickened, and it is not uncommon for many of the glomeruli to be reduced to small rounded masses of fibrous tissue in the centre of which are the remains of the glomerular tuft in a condition of hyaline degeneration. The epithelium lining the glomerular chamber frequently presents no very obvious changes. The tubules are in places dilated, but over large areas of the kidney they are contracted and the diminution in the size of the whole organ is very largely dependent on this contraction. Where the tubules are dilated they are frequently lined by cubical glass-like epithelium. Here and there tubules may be found lined with

more or less normal epithelium. In some parts the dilatation of the tubules is sufficiently marked to produce cysts, and these are commonly lined by a low, flattened epithelium. In many parts the epithelium is shed and occupies the lumen of the tubules. The connective tissue is considerably increased in amount, and septa may be seen passing in from the capsule towards the centre of the organ. The vessels are frequently unduly prominent and show very marked thickening of their coats, the thickening being mainly dependent on an overgrowth of fibrous tissue in the sub-endothelial layer, but the muscular coat may have undergone some increase in thickness. Although the renal vessels are commonly affected to a marked extent in this form of Bright's disease, the degree of arterial degeneration does not vary *pari passu* with the shrinkage of the kidney. Cases of very small contracted kidney may be seen where the arterial changes are less well marked than in larger specimens of the same malady.

Both in acute and in all forms of chronic Bright's disease lesions are frequently found in other organs of the body. Thus secondary inflammations, pleurisy, pericarditis, peritonitis, and pneumonia are common, pericarditis especially so, both in the dry form and with effusion. Where effusion is present it may be serous, sanguinolent, hæmorrhagic, or purulent. Both in acute and chronic Bright's disease the heart and blood-vessels often show signs of disease, and the heart may show definite signs of hypertrophy in as short a time as six weeks from the onset of acute Bright's disease. Although, speaking broadly, the cardiac hypertrophy is most marked in cases of contracted white kidney, this is not invariably the case, and in some instances of large white kidney very considerable cardiac hypertrophy is found. The degree of the cardiac hypertrophy would seem to be correlated rather with the degree to which changes in the sub-endothelial coat of the arteries are widespread. It certainly is not directly correlated with the diminution in the size of the kidney, as cases of extremely contracted white kidney may be seen with little or no cardiac hypertrophy, and, on the other hand, this may be marked and even cause death from cerebral hæmorrhage in cases of so-called large white kidney.

SYMPTOMS.—The onset of acute Bright's disease is usually sudden, and the initial symptom may be the occurrence of dropsy. In other cases general symptoms, such as fever, headache, vomiting, occur at the onset, and pain or diffuse aching in the back may also be present; pain, however, is not usually a prominent symptom. The dropsy is most marked in the subcutaneous tissues, more especially over the sacrum, and in vulva and scrotum; puffiness of the eyes is also well marked. In some cases the anasarca affects almost the whole of the subcutaneous tissues from the commencement. In all cases of acute Bright's disease the urine undergoes profound changes, and in some cases the urinary changes are the first to attract attention, the general symptoms being ill marked. The urine is diminished in quantity, and in some cases suppression very soon occurs; it is more usual, however, for the suppression to be partial. Where complete suppression occurs severe uræmic symptoms, such as coma and convulsions, are very rapidly developed and death soon takes place. The urine is generally smoky in acute Bright's disease, and it frequently contains large quantities of

blood, which gives it a uniform red colour; the blood-pigment may however have undergone changes so that the urine is dark or even porter-coloured. The urine of acute Bright's disease deposits casts and blood-corpuscles in large quantities. Albumen is always present, and commonly the urine becomes solid on boiling during the acute stage of the disease. Occasionally the quantity of albumen is less than this, but it is always large. The excretion of urea is diminished, but this is in part dependent on the diminished appetite, nausea, and vomiting which are commonly present in the disease. In some cases of acute Bright's disease the urinary changes are exceedingly well marked, the urine being highly albuminous, scanty, and containing large quantities of blood, and yet dropsy and the general symptoms of the disease may be comparatively slight. In others dropsy and the general symptoms are more prominent characteristics, but the urine, though highly albuminous and scanty, does not contain large quantities of blood. Uræmic symptoms of different degrees of severity occur in all forms of acute Bright's disease, and gastric symptoms such as anorexia, nausea, and vomiting are almost always present; and in the severe forms of the malady accompanied by suppression of urine the more serious uræmic manifestations such as delirium, dyspnoea, coma, mania, epileptiform seizures, are commonly present, and death in acute Bright's disease is not infrequently dependent on these uræmic complications.

Anæmia is always a prominent symptom and is developed rapidly, and the skin of the body is dry and harsh.

Epistaxis, hæmorrhage into the gums, and a general sponginess of the gums are frequently present.

Secondary inflammations such as pleurisy, pneumonia, pericarditis are common. Cardiac dilatation apart from the occurrence of pericarditis may also occur even early in the course of the disease.

The pulse in most cases of acute Bright's disease soon shows signs of high tension, and in the course of a few weeks, if the disease does not subside, the heart may show signs of evident enlargement dependent on hypertrophy.

Retinal changes are not so common in acute as they are in chronic Bright's disease, but papillitis, hæmorrhages, and retinitis may occur.

It is probable that the acute Bright's disease following scarlet fever and characterised by marked changes in the glomeruli, is more frequently accompanied by hæmaturia than the Bright's disease said to be due to exposure to cold.

Chronic Bright's disease.—As mentioned above a very large proportion of cases of Bright's disease are chronic from the beginning, but in a certain proportion the malady directly follows on the acute disorder or is a sequel to it; in other words some cases of acute Bright's disease pass on to the chronic stage without the urine regaining its normal characters, in others the chronic disease begins insidiously after an attack of the acute disease and with an intervening period of good health.

The initial symptoms of chronic Bright's disease present great variety. In a large group of cases the initial symptoms are a progressive failure of strength together with considerable wasting. In others the occurrence of dropsy more or less suddenly is the first sign of ill health. In others uræmic symptoms such as nausea, vomiting, and cramps, and in others,

severe headache, palpitation, and symptoms dependent on the disturbance of the circulatory system are those which first attract attention.

In the form of the disease associated with the so-called large white kidney dropsy is not only a prominent but often a very persistent feature of the illness and produces the well-known bloated appearance associated with a certain group of cases of chronic Bright's disease. Dropsy is not only well marked in the subcutaneous tissues but often also in the serous cavities, more especially the pleura. The dropsical fluid is of low specific gravity and contains relatively a small amount of albumen, much less than that seen in cardiac dropsy. The subcutaneous dropsical fluid contains a smaller percentage of proteins than that seen in the fluid in the serous cavities.

Anæmia is a marked feature of the malady, the skin and mucous membranes being pale and the complexion pasty.

Purpuric hæmorrhages in the skin are not uncommon, and in severe cases similar hæmorrhages in the mucous membrane of the mouth are also present. Epistaxis may also occur.

Patients with chronic Bright's disease are always weak and frequently considerably wasted, but the emaciation is often masked by the presence of dropsy. Uræmic symptoms are usually present in all cases that are severe, and are especially apt to assume a gastro-intestinal form, so that nausea, vomiting, hiccough are commonly present in all but the slightest forms of the disease. In the more serious forms dyspnoea, drowsiness, delirium, and epileptiform seizures may occur, and death in chronic Bright's disease is not uncommonly due to such complications, although fatal uræmic seizures are more frequent in association with contracted white kidney than with the so-called large white kidney. Cardiac symptoms such as palpitation, præcordial anxiety and distress, and shortness of breath are also usually present, and patients presenting these symptoms usually show signs of cardiac hypertrophy and dilatation and not uncommonly of mitral regurgitation dependent on degenerative processes in the ventricle leading to extreme dilatation.

The pulse usually shows signs of high tension, but not to the degree that is seen associated with the contracted white kidney. In cases where high tension is marked, a throbbing headache, greatly aggravated by changes of posture, is often present. Degeneration of the vessels can often be detected by ophthalmoscopic examination, which reveals not only the wiry and thickened arteries, but also the presence of albuminuri retinitis, hæmorrhages, and papillitis. See OPHTHALMOSCOPE IN MEDICINE, Coloured Plate.

In the large white kidney the urine is diminished in amount when dropsy is present, twenty ounces or less being secreted in the twenty-four hours. The urine is usually pale in colour and contains a large but variable amount of albumen, so that it may deposit after boiling as much as a half, three-quarters, or even become solid. Casts are usually present in abundance, especially hyaline and granular, but in addition casts containing renal epithelial elements and showing signs of degeneration are frequently found. Fatty casts are especially of grave import. The urine is always greatly diminished in quantity when dropsy is present, and fluctuations in the quantity of urine are often associated with fluctuation in the amount of the dropsy.

In the form of chronic Bright's disease where the kidneys are contracted, described above as contracted white kidneys, the symptoms are somewhat different; dropsy in these cases is not only not a marked symptom, but it may be completely absent, and when present it is generally slight in amount. On the other hand, anæmia and nutritional symptoms such as wasting and loss of strength are prominent, and such patients usually come under observation on account of a progressive failure in health, or else owing to the sudden onset of uræmic symptoms. Many such patients seek advice on account of persistent headache, and on examination of the fundus oculi albuminuric retinitis is found.

Uræmia is in the opinion of the writer extraordinarily prone to occur as a complication or even as an initial symptom in these cases. In other words the malady is apt to run a latent course until the onset of uræmic symptoms denotes the gravity of the underlying disease. Many such patients present no symptoms of ill-health until a series of epileptiform seizures or the occurrence of delirium, drowsiness, and coma attract attention to the renal lesion. Cardio-vascular degeneration is usually well marked in such cases; the heart is obviously hypertrophied and a high-tension pulse is present. Such patients not uncommonly suffer from cerebral hæmorrhage.

Albuminuric retinitis and papillitis are marked features in these cases and are more frequently present than in the other form of chronic Bright's disease. The urine is abundant, pale, of low specific gravity, but contains usually a considerable quantity of albumen, e.g. a quarter, a third, or even a half.

It is possible that some of the cases presenting these symptoms are to be regarded as the later stages of the so-called large white kidney, but, as insisted on above, many of these cases give no history of dropsy, and the whole illness is latent, or gradual and insidious.

COMPLICATIONS.—Many of the complications that occur in Bright's disease have been enumerated among the symptoms, as, for instance, the secondary inflammations and the occurrence of uræmia. Some, however, are of sufficient importance to merit separate mention.

Nausea and vomiting frequently occur and are dependent usually on uræmia. Sometimes, however, actual *gastritis* is present, leading to severe and incessant vomiting, and is thought to be dependent on the vicarious excretion by the stomach of retained urinary constituents such as urea.

Profuse *diarrhœa* dependent on enteritis is also not uncommon, and in a small proportion of cases ulcerative colitis is present in the large intestine and in the vicinity of the cæcum. *Peritonitis* is also occasionally seen as a complication of Bright's disease, and it may occur with or without effusion.

Pericarditis is a very serious and frequent complication of all forms of Bright's disease, and is more especially important from the fact that it is apt to be latent and so not produce marked symptoms. In some cases the effusion in pericarditis has been found to be sterile, but it is most frequently dependent on secondary microbic infection.

Phthisis is occasionally seen in cases of Bright's disease, or more usually Bright's disease is seen as a complication of phthisis; and although waxy disease of the kidney is especially liable to be present under these circumstances ordinary chronic Bright's disease is sometimes associated with phthisis.

Inflammatory complications such as pneumonia

and pericarditis and such diseases as phthisis may run an afebrile course when associated with chronic renal disease.

The *cardiac hypertrophy* usually present may result in the development of such cardiac lesions as dilatation, mitral regurgitation; and the arterial thickening and high tension may lead to the development of *cerebral hæmorrhage*. This is more especially apt to occur in the contracted white kidney, but is also seen in the other form of chronic Bright's disease.

Not only are *secondary inflammations* apt to occur in patients suffering from Bright's disease, but erysipelas and cellulitis may develop in the subcutaneous tissues, more especially after incision.

Cutaneous rashes, eczema, papular eruptions, erythematata, and bullæ are not uncommonly associated with chronic Bright's disease and more especially when uræmia is present, and occasionally these rashes are seen as prodromal or initial manifestations of uræmia.

DIAGNOSIS.—The diagnosis of acute Bright's disease is readily made in the majority of instances owing to the presence of dropsy together with the changes in the urine characteristic of acute inflammation, such as the presence of blood, albumen, and casts. Difficulties occasionally present themselves owing to the absence of dropsy in some cases and owing to the fact that blood may be present in the urine in other conditions besides acute Bright's disease. See KIDNEY, Diseases of.

Acute Bright's disease may have to be distinguished from (1) transitory nephritis seen in acute febrile illnesses, (2) hæmorrhagic infarction, and (3) passive congestion of the kidney secondary to heart-disease.

In the nephritis of acute febrile diseases dropsy is usually absent, and if hæmaturia be present the amount of blood is usually small; in the vast majority of instances hæmaturia is not present.

In hæmorrhagic infarction the urine not uncommonly contains a considerable quantity of blood and albumen, and the onset of the condition may be sudden and accompanied by pain and fever, so as to produce a superficial resemblance to the onset of acute nephritis. The effects however are usually transitory, and there is no dropsy. It is important to differentiate between hæmorrhagic infarction and acute Bright's disease, more especially in cardiac cases, as the prognosis of the two conditions is very different.

In passive congestion of the kidney blood and albumen may be present in the urine, and inasmuch as the condition arises usually in cases of heart-disease dropsy is frequently present, and it may be difficult in such cases to determine accurately whether acute inflammation is or is not present. In passive congestion the hæmaturia is usually though not always scanty, in acute inflammation it is more often abundant. In passive congestion hyaline and blood-casts are commonly present, in acute Bright's disease casts containing definite renal elements occur, and in this way a differential diagnosis may be made. Further, the dropsy of cardiac disease is usually different in its distribution from that of renal disease.

Chronic Bright's disease and granular kidney may sometimes be confounded with acute Bright's disease, inasmuch as in both the former conditions hæmaturia profuse in amount may occur, and in some cases this hæmaturia is dependent on hæmorrhage from the mucous membrane of the pelvis of the kidney. This is more especially the case in the granular kidney, and

the contracted white kidney, and such cases present considerable difficulties in diagnosis. Usually the presence of cardio-vascular changes and of albuminuric retinitis will afford evidence that the patient is not suffering from a primary attack of acute Bright's disease.

It is said that some cases of acute Bright's disease occur where, notwithstanding the presence of dropsy, there is not only no blood in the urine but no albumen. In these cases however the absence of albuminuria is usually temporary.

The main difficulty in the diagnosis of chronic Bright's disease is to determine accurately what form of chronic Bright's disease is present. In addition to this it is sometimes not easy to differentiate between some forms of chronic Bright's disease and the so-called physiological or *cyclical* albuminuria.

Chronic Bright's disease when accompanied by dropsy is usually readily diagnosed. Mistakes are most apt to occur in the form of the malady described above as the contracted white kidney where dropsy is absent. If the urine is not carefully examined in such cases, the presence of headache and vomiting may lead to the error of some intra-cranial disease being suspected, and this is especially liable to occur if some cerebral complication such as hemiplegia be actually present. Uremic manifestations such as epileptiform fits are not uncommon as initial manifestations of the contracted form of white kidney, and in such cases the error of diagnosing epilepsy, where the much more serious disease is really the cause of the symptoms, is not unusually made.

Examination of the fundus oculi and the detection of cardio-vascular changes, together with the examination of the urine, will generally enable a differential diagnosis to be made, but it must be remembered that albuminuria may occur in epilepsy. See EPILEPSY.

The presence of considerable wasting, together with the occurrence of hæmaturia in some cases of contracted white kidney, has led to this variety of chronic Bright's disease being confounded with malignant disease of the kidney.

Physiological albuminuria can usually be diagnosed owing partly to the absence of signs implicating the cardio-vascular system and the fundus oculi, and also owing to the variability of the albuminuria and the influence of diet, exercise, and posture upon it.

Cases of chronic renal disease are occasionally seen with marked symptoms of uræmia and disturbance of nutrition, such as great wasting, without the presence of albumen in the urine, although it is probable that in such cases the absence of albumen is temporary. These cases present great difficulties in diagnosis, and mistakes are occasionally unavoidable.

In a few cases pigmentation in chronic renal disease occurs to such a marked degree as to produce a superficial resemblance to that seen in Addison's disease. See ADDISON'S DISEASE.

PROGNOSIS.—Acute Bright's disease complicating scarlet fever has often a more serious prognosis than that depending on other causes, although the ultimate outlook in these latter cases may also be unfavourable. In other words, acute Bright's disease following scarlet fever is more immediately dangerous, but that following exposure to cold or dependent on alcoholism may lay the foundation for subsequent chronic Bright's disease.

The unfavourable symptoms in acute Bright's disease are the persistence and increase of the dropsy

and anæmia, together with the development of uræmic symptoms associated with the suppression of urine.

Acute uræmia occurring in acute Bright's disease is, however, by no means invariably fatal.

In a considerable proportion of cases of acute Bright's disease the dropsy subsides, the urine ceases to be albuminous, and the patient regains health. In a certain proportion of instances, however, the condition persists and becomes chronic. Even in cases where the urine regains its normal composition, the patient runs considerable risks of a recurrence of the trouble, as the result of indiscretions in diet or exposure to damp and cold.

The prognosis of chronic Bright's disease, speaking generally, is unfavourable, although patients may live for many years. The prognosis is very uncertain owing to the fact that patients suffering from chronic renal disease even when apparently in good health may develop complications rapidly fatal, such as cerebral hæmorrhage or acute uræmia. Cases are seen, however, where patients may for ten or even twenty years pass a urine scanty in amount and containing large quantities of albumen. It is usually stated that where the condition has persisted for as long as a year recovery does not occur. This statement, although doubtless generally true, is not of universal application.

The presence of signs of marked cardio-vascular changes and of albuminuric retinitis is unfavourable, and it is usually said that when albuminuric retinitis is present death occurs generally within a year. This, however, is not true of all cases, as exceptionally life may be prolonged for as long as five, six, or even seven years after the presence of albuminuric retinitis has been detected.

TREATMENT.—In acute Bright's disease the patient must be kept warm and confined to bed until all the acute symptoms have subsided. The diet must be restricted to one as simple in character as possible, such as milk, gruel, and barley-water in small quantities. During the height of the disease from one to three pints of milk in the twenty-four hours is sufficient. Milk should be given freely diluted with soda-water or barley-water. Stimulants should not be given. The activity of the skin must be promoted by hot drinks, the wet pack, and hot-air baths (see BATHS). The temperature of the bath should be from 120° F. to 170° F., and they should not be persisted in if they cause cardiac weakness. Sweating may be also promoted by the administration of jaborandi or pilocarpine, but it is not advisable to push these drugs to the extent of producing their well-known toxic symptoms, and it is often difficult to procure efficient sweating unless this be done. The combination of hot-air bath with the administration of jaborandi is often useful.

The partial suppression of urine that is present in all severe cases may be treated by the administration of diluents, but it is doubtful whether the stimulant diuretics are of much use or even suitable for these cases. Citrate of potassium and also nitrate of potassium may be used. Caffeine, however, is probably not suitable.

The cardiac weakness which is sometimes present during the early stages of the disease may be treated by the administration of digitalis and strychnine.

The dropsy may be treated by measures directed to promote the activity of the skin and of the bowels, and such simple drugs as the saline purges, sulphate of sodium, phosphate of sodium,

and sulphate of magnesium, may be used for this purpose. Jalap is also useful, but violent purgation is not advisable in acute Bright's disease, inasmuch as enteritis is one of the complications of the malady, and a profuse diarrhoea started by the administration of drugs may become uncontrollable and greatly increase the weakness.

Uræmic symptoms must be treated on the same lines as the dropsy, by promoting the activity of the skin and the bowels, but if they are severe these methods may fail, and then venesection and saline transfusion are useful. Chloroform may be used to diminish the severity of the uræmic convulsions, and morphine also may be used with discretion for this purpose, but is held by some authorities to be dangerous, and many forbid its use altogether.

The severe anæmia that accompanies acute Bright's disease and persists during the convalescence must be treated by the administration of iron and arsenic.

In convalescent cases the diet should be gradually increased. Fish and white meats should be given first, and all highly seasoned and elaborately cooked articles of food avoided.

The treatment of chronic Bright's disease is in some respects similar to that of acute, in that if dropsy be present, the activity of the skin must be promoted by the same methods. If the disease is of recent origin or severe, the patient should be kept in bed and the diet restricted to milk. In chronic Bright's disease a larger quantity of milk will be required than in the acute malady, since four pints *per diem* is a minimum quantity for an adult. A milk-diet is also indicated in all cases of chronic Bright's disease presenting uræmic symptoms. The milk-diet should be persisted in for some weeks, but if under this treatment the dropsy and the other symptoms of the disease do not improve, it is probably advisable to increase the diet to a moderate extent, allowing fish and white meats, and if improvement occurs the ordinary meats may be allowed. Many cases of chronic Bright's disease, where anæmia is a marked symptom and where the disease is of some duration, progress more favourably if given a moderate diet, and it is probably unadvisable to treat all cases of chronic Bright's disease with a rigid milk-diet. In all cases of chronic Bright's disease highly seasoned articles of diet and rich concentrated foods should be avoided, and at all times such patients should take only small quantities of meat. Alcohol is probably harmful in all forms of chronic Bright's disease, and should be only given, if at all, in small quantities and freely diluted.

The dropsy of chronic Bright's disease is often very persistent, and in some cases it is of mixed origin, being partly true renal dropsy, and partly cardiac dropsy dependent on cardiac failure secondary to the renal disease. In some cases where the dropsy is not relieved by hot-air baths and other measures directed to increase the activity of the skin, incisions over the malleoli may become necessary, but in cases of renal disease extra precautions require to be taken to prevent septic complications.

The anæmia of this disease is often very marked and should be treated by the administration of iron and arsenic.

BROMIDROSIS (*βρώμος*, a stench; and *ἰδρῶς*, sweat).—A term for fetid perspiration. *See* PERSPIRATION, Disorders of.

BROMISM.—*See* DRUG-ERUPTIONS.

BRONCHI, Diseases of.—SYNON.: *Fr. Maladies des Bronches*; *Ger. Bronchien-Krankheiten*.—The diseases of the bronchi will be discussed in the following order:—1. Acute inflammation; 2. Chronic inflammation; 3. Plastic inflammation; 4. Dilatation; 5. Narrowing or obstruction; 6. Cancer.

1. Acute Inflammation—Acute Bronchitis—Acute Bronchial Catarrh.

DEFINITION.—An acute inflammation of the bronchial tubes.

ÆTIOLOGY.—The causes of acute bronchitis may be classed as (*a*) *predisposing*, and (*b*) *exciting*.

(*a*) *Predisposing causes.*—Of these age is one of the most important. The disease is most frequently met with in the young and the old; and in these subjects it assumes its most serious characters. The imperfectly developed thorax of the infant, and the diminished vitality of the aged, seem to render them especially liable to attacks of bronchitis, and to make the disease exceptionally fatal in them. Sex appears to have no influence as a predisposing cause. The habits of life have an important influence in the causation of bronchitis. The practice of living in heated rooms, especially where gas is largely consumed, and of breathing the vitiated atmosphere produced by the assemblage of large numbers of persons in a single room, is undoubtedly a fertile predisposing, as well as exciting, cause of the complaint; so also is the practice of keeping children too much within doors on the one hand, or, on the other, of exposing them to inclement weather when improperly clad. The state of the general health exercises a powerful influence. A weakly constitution, or one weakened by overwork, improper food, &c., predisposes to bronchitis; while such affections as Bright's disease, gout, and diseases of the heart, alike favour its occurrence. The climate most favourable to the production of bronchitis is probably that which is at the same time both cold and damp, and where sudden variations of temperature occur. The seasons of the year in which it prevails most are the late autumn, the winter, and the early spring.

(*b*) *Exciting causes.*—Although undoubtedly cold directly applied to the surface of the body is in a large number of cases the exciting cause of bronchial inflammation, still the transition from cold to heat—passing from a cold atmosphere to a heated one—is an important factor of the disease. There can be little doubt that bronchitis is often produced directly by the effects of heated and vitiated air on the bronchial mucous membrane. Bronchitis may also be caused by the direct action of irritants contained in the air—as irritant vapours, minute particles of steel, cotton, or ipecacuanha, and the pollen from flowering plants. The toxins which are present in the system in the course of specific febrile affections often act as exciting causes of the disease; as do also the poison of syphilis, and the altered condition of the blood produced by gout. Bronchitis, moreover, must be regarded as a constant accompaniment of influenza. According to Ritchie acute bronchitis is an infective disease. The bronchitic secretion in the smaller tubes contains in every case many varieties of bacteria. In some the number of these is so great as to suggest a causal relationship, especially in the case of the *Diplococcus pneumoniae* and the *Streptococcus*.

ANATOMICAL CHARACTERS.—The mucous membrane is mainly affected in acute bronchitis, but morbid changes may be produced in the deeper structures. The mucous membrane is red—the redness being arborescent, streaked, or mottled, but not usually spread uniformly over a large surface. The injected condition of the membrane does not, as a rule, extend into the finer bronchial tubes, but in some cases where there have been frequent attacks of inflammation, these tubes have a red appearance. The membrane is sometimes thickened and soft, but ulceration is very rare. The tubes are generally found more or less filled with secretion, either frothy mucus, muco-pus, or even actual pus. Sometimes the secretion is very abundant, filling all the tubes. Fibrinous masses are occasionally met with, which may form casts of the tubes. Collapse of portions of lung-substance is not infrequently found, as are also patches of lobular pneumonia. The venous system and the right side of the heart are overloaded, and the blood is dark. In many cases fibrinous deposits are found in the cavities and great vessels of the heart.

In discussing the pathology of bronchitis, it is necessary to refer to the distribution of the bronchial blood-vessels. The bronchial arteries when they have fairly entered the lungs have no accompanying veins. The so-called bronchial veins are some small vessels which return the blood supplied to the structures about the roots of the lungs. The blood which is supplied to the bronchial tubes, when they have commenced their divisions, passes into radicles of pulmonary veins, and is returned directly to the left side of the heart. It is uncertain whether there are any anastomoses between the bronchial arteries and the pulmonary artery. If such communication exist, it is only slight. The blood of the bronchial arteries, after supplying the mucous membrane and other structures of the tubes, passes, either wholly or in a very large part, to the left side of the heart, not having circulated through the aerating portion of the lungs. The circumstances of this anatomical arrangement are most important from a practical point of view. Anything which embarrasses the circulation on the left side of the heart—such as mitral regurgitation—must necessarily cause a very loaded condition of the bronchial vessels; and all physicians are familiar with the form of bronchitis which is so common in these cardiac affections. The congested mucous membrane, and the profuse bronchial secretion, are the result of the direct impediment to its circulation which the blood meets with, from passing at once into vessels which go straight to the left side of the heart. The relief often afforded in this form of bronchitis by the administration of digitalis is explained by the circumstance above referred to.

SYMPTOMS.—The symptoms of acute bronchitis differ according as the inflammation is located in (a) the large and medium-sized tubes, or (b) the small ones. To the latter form of the affection the name of *capillary bronchitis* has been given.

1. Acute bronchitis of the *larger tubes*.—The attack is usually ushered in by symptoms of catarrh—sneezing, lachrymation, a sense of fullness about the nose and eyes, with frontal headache; the throat becomes dry and sore, and then increased secretion sets in; the follicles at the back of the pharynx become enlarged; the upper part of the larynx is often involved, there being slight hoarseness; and the affection gradually creeps down into the

bronchial tubes. The disease is not ushered in by decided rigors, but chills and sometimes shiverings are experienced; the pulse is not much affected, but its frequency is increased in some cases; there is a general sense of malaise, as well as a want of energy. When the disease has set in fully certain local symptoms are found. More or less pain is felt behind and above the sternum; the sensation is increased by a deep inspiration; the pain shoots at times over the chest in the direction of the larger bronchial tubes; and there is a tickling or unpleasant irritation felt behind the sternum, which gives rise to a cough. Dyspnoea is not a marked feature of this form of bronchitis; it exists, however, sometimes; and in the most severe cases a sense of oppression, weight, and tightness about the chest is experienced. Cough is one of the earliest and most prominent symptoms; it is at first dry, and there is usually at this period some hoarseness. The cough is paroxysmal, and often very violent; it becomes attended with expectoration as the disease progresses. This varies at different stages of the affection; at first watery and frothy, and almost transparent, it becomes, as the disease progresses, more consistent, viscid, and opaque, consisting successively of mucus, muco-pus, and pus; it is sometimes distinctly nummulated. Small streaks of blood are occasionally seen mixed with the sputa. Examined under the microscope the sputa are found in the early stages of the disease to contain epithelial cells from the mucous membrane; and, later, many of the so-called exudation-corpuscles, molecular and granular matter, pus-cells, and occasionally blood-discs.

In the milder cases of this form of bronchitis there is but little general disturbance; and even in the more severe cases the febrile reaction is not usually very great. The pulse rises a little, but does not become very frequent; the temperature rarely becomes high; there is in many cases but little interference with the appetite. A general feeling of depression, which in some cases is very marked, is usually experienced.

2. Acute bronchitis of the *smaller tubes*.—*Capillary bronchitis*.—This is a very formidable disease. It attacks the finer bronchial tubes, and probably extends to their smallest ramifications. Its symptoms are very grave. Some of the worst cases of capillary bronchitis are met with in connection with emphysema of the lungs. It may be an extension of inflammation from the larger tubes; or the capillary tubes may be attacked simultaneously with the larger ones, or alone. The early symptoms are more severe than those of ordinary bronchitis, and rigors are more common. Dyspnoea is marked; it may vary from mere rapid respiration to constant or paroxysmal orthopnoea. The respirations may rise to fifty in a minute. Cough is almost continuous, at times becoming very violent and most distressing. Expectoration is attended with difficulty. The sputa soon become very abundant, and rapidly assume a purulent character; or they are very viscid and ropy. *See* SPUTUM, Examination of.

The general symptoms are very severe. The temperature may reach 103° F. or even higher, though it is rarely as high as in acute tuberculosis or pneumonia; and the pulse may be 120 or 140. There are often profuse perspirations, and in some cases excessive debility is felt. If the disease progresses unfavourably, symptoms of very imperfect

aëration of the blood come on. The face becomes turgid and bloated, the lips and ears get livid, the veins are distended, the temperature falls, cold clammy perspirations break out, the pulse becomes very small and rapid, delirium supervenes, the respiration is shallow and catching, and the patient dies of asphyxia, or from the presence of fibrinous clots in the heart and great blood-vessels.

PHYSICAL SIGNS.—The physical signs of both forms of acute bronchitis may be referred to together. Inspection reveals little of practical value in simple bronchitis. The form of the chest is not altered. In severe cases the abdominal movements are in excess. The costal movements are frequently those of elevation rather than expansion. In extreme cases the lower end of the sternum and the connected cartilages sink with inspiration; while the expiratory movements are slow, laboured, and inefficient. If the hand is applied to the chest, rhonchal fremitus may be often felt, sometimes over a large area. The percussion-sound may be somewhat exaggerated from over-distension of the lungs, especially in children; not appreciably altered; or deficient in resonance, owing to the accumulation of secretion at the bases of the lungs, to œdema or congestion (as in typhoid fever), or to pulmonary collapse. In young children a sound resembling the cracked-pot sound may be occasionally produced, variable in site. The sounds heard on auscultation vary according to the stage of the disease. The breath-sounds are loud when the tubes are free; when the latter are plugged by secretion, they often become feeble or even totally suppressed, from closure of a tube leading to a portion of the lung. The adventitious sounds of bronchitis include the various rhonchi and râles; the dry rhonchi are heard in the early stages of the disease for the most part, but when once secretion has set in, the moist râles are more or less extensively heard, depending for their character on the size of the tubes which are the seat of inflammation. Thus they are called *mucous* when produced in the large tubes, *sub-mucous* and *sub-crepitant* when produced in the finer ones; the latter term being used to characterise the râles of capillary bronchitis. When the large bronchial tubes are filled with a secretion which is not viscid, the sounds may have a rattling character. The various rhonchi may be heard over different parts of the lungs at the same time, according to the seat and stage of the bronchitis. In capillary bronchitis sub-crepitant râles, accompanying inspiration and expiration, are abundantly heard, especially towards the bases of both lungs. As a rule there is no displacement of organs in bronchitis, but the diaphragm is sometimes depressed from great distension of the lungs, and the heart is occasionally displaced towards the right.

DIAGNOSIS.—The diagnosis of acute bronchitis, except in a few instances, presents no great difficulty. In the early stages of whooping-cough it is impossible to decide whether the case is one of simple bronchitis or not, but subsequently the paroxysmal character of the cough settles the point. In some cases of bronchitis occurring in children the breathing may resemble that of croup; but here the presence of catarrh, the wheezing nature of the respiration, the absence of much fever, the characters of the sputa—obtained by wiping the back of the tongue—and their freedom from membranous shreds, and the physical examination of the chest indicating the presence of rhonchi, will be

sufficient to establish a diagnosis. From laryngitis the discrimination is not difficult.

Pneumonia may generally be easily diagnosed from capillary bronchitis, with which form it can perhaps be alone confounded. Capillary bronchitis is not ushered in, as pneumonia usually is, by a well-marked and prolonged rigor; the general febrile disturbance is less, and the temperature not so high; moreover the absence of dulness on percussion, and of increased vocal resonance and fremitus, will aid in the differentiation. From lobular pneumonia in children the diagnosis is not always easy. In this disease there is often no dulness to be perceived on percussion; while, on the other hand, dulness may exist in bronchitis from pulmonary collapse.

The diagnosis of capillary bronchitis from acute phthisis often presents difficulties. The main points to be relied on, independently of the family history, which may aid, are that in capillary bronchitis the fever is less and the temperature lower; signs of asphyxia soon come on; and there is free expectoration of muco-purulent matter, from which the tubercle-bacilli are absent. In one form of acute phthisis there is evidence of pneumonic consolidation, followed by signs of the formation of cavities. In the miliary tubercular form there are in many cases scarcely any physical signs except râles, most marked at the apices of the lungs. Here, however, the diagnosis may be aided by the examination of the sputa under the microscope, which may reveal the presence of tubercle-bacilli.

PROGNOSIS, DURATION, TERMINATION, AND MORTALITY.—The prognosis in an ordinary case of bronchitis is favourable, but should always be guarded when the disease occurs in the very young or the aged. In the milder forms the affection may last only a few days, or two or three weeks. Severe cases are more protracted. The disease may terminate in perfect recovery, in death, or by passing into the chronic form. It may be the starting-point of emphysema of the lungs, or of certain forms of phthisis. The mortality is much influenced: (1) by age, being greatest in the very young and the very old; (2) by the previous state of health, which, if lowered by any circumstances, will render recovery more doubtful; (3) by the extent of the inflammation, especially when the disease is of the capillary form; (4) by the existence or non-existence of any organic disease of the heart, lungs, or kidneys; (5) by the disease being epidemic in connection with influenza or otherwise; and, lastly, by the time the case has come under treatment, whether early or late.

TREATMENT.—In the treatment of bronchitis care must be taken to ascertain whether the disease is secondary to some organic affection, or the result of mechanical irritation, or of the presence of gout or rheumatism in the system, or of influenza; or whether it arises as a primary disease. The treatment of the disease as a primary affection will be considered first.

In an ordinary case of acute bronchitis the patient should be confined to his room, and, if the case is at all severe, to his bed. The temperature of the apartment should be maintained at from 60° to 65° F. In the early stages of the attack it is well to allow the air of the room to be more or less saturated with steam. A free action of the skin should be promoted; and for this purpose warm drinks, with or without some form of alcohol or

some diaphoretic medicine, may be given; or a hot-air bath may be used in bed. Great relief is often experienced from the application of a large mustard or mustard and linseed-meal poultice to the chest, but severe counter-irritation is to be avoided; and it is well, if mustard is applied first, to apply immediately afterwards a large hot linseed-meal poultice, to be renewed every few hours. This constant application of warmth and moisture to the chest is often productive of very great relief to the symptoms.

It is generally desirable to act on the bowels, and a mercurial, followed by a saline purgative, will often be of great service. In the old and debilitated, as also in the young, all lowering treatment must, however, be avoided. In the early stages of the affection, before secretion has commenced, and when the mucous membrane is dry and the cough hard, diaphoretics with *ipeacuanha* may often be given with advantage; but as soon as secretion is fairly established, carbonate of ammonium, spirit of chloroform, ether, *cascarilla*, *senega*, or similar drugs should be administered. Indeed in almost every stage of bronchitis carbonate of ammonium is one of the most valuable remedies we possess. Care should be exercised, especially with the aged, that nothing should be given which will so nauseate as to prevent food being taken. In the exhibition of medicines to alleviate the cough, regard must be had to the condition of the patient and the stage of the disease. Opium in all its forms should be given with caution, and is generally inadmissible, especially in the young and old. It no doubt often succeeds in checking cough, but in doing so it also checks expectoration, and causes an accumulation in the bronchial tubes, which sometimes becomes very dangerous to life. Chloral hydrate in small doses is often of great use for relieving cough, and it may be combined with oxymel of squill. It has also a good effect in allaying spasm of the tubes, if this exist. In some cases of bronchitis the question of procuring sleep becomes an important one. Chloral hydrate may be given with safety, and the recovery of a patient may sometimes be dated from the sleep which this agent procures.

Alcoholic stimulants, except in the early stages, and in certain cases dependent on a gouty or rheumatic condition, should usually be given in smaller or larger quantities. They increase expectorating power, and ward off the tendency to asphyxia. In the old they are especially called for, and, together with carbonate of ammonium, should form the main therapeutic agents to be relied on. In the treatment of capillary bronchitis, ammonia and alcoholic stimulants should be exhibited from the commencement, and the quantity must depend on the symptoms of each case. There is one source of danger in capillary bronchitis which should always be borne in mind, viz. the formation of fibrinous clots in the heart and great blood-vessels. These deposits become the proximate cause of death in many cases, and they are especially liable to form when there is emphysema of the lungs. Their presence may often be diagnosed during life from the respiration becoming very rapid, shallow, and laboured; from the pulse being quick, weak, and small, although the heart may at the same time be felt beating vigorously; from the voice becoming feeble, and the mental faculties seriously impaired. After death a large portion of the cavities of the heart may be found occupied by these deposits, the calibre of the pul-

monary artery and the aorta being also materially diminished by them.

In many cases of bronchitis when the acute symptoms have passed off, but the secretion continues profuse, as well as in those cases called bronchorrhoea, the exhibition of iron is often of great service. It seems to give tone to the relaxed capillaries of the mucous membrane, and to diminish the secretion. It may be given in combination with carbonate of ammonium, in the form of the ammonio-citrate; or the tincture of the perchloride with ether or spirit of chloroform may be employed, or the ethereal tincture of the acetate (*Ph. Ger.*), which is a very valuable preparation in some cases.

Inhalations are useful for allaying cough, in the earlier stages of the affection, or for the relief of spasm. In some cases of severe bronchitis where asphyxia has been threatened, recovery has followed the exhibition of large doses—half an ounce—of oil of turpentine. In this dose, however, it sometimes produces alarming symptoms, and it is perhaps better to exhibit it in smaller quantities tentatively. An emetic may be serviceable, especially in children, if the tubes are much loaded. Children suffering from severe attacks of bronchitis should not be allowed to sleep long, for fear of dangerous accumulation in the tubes, and care should be taken that the secretions do not collect about the back of the mouth.

Patients should not be kept on a low diet even at the beginning of an attack, and as the disease progresses the quantity of food allowed may be increased according to the appetite. In the treatment of gouty bronchitis, colchicum and the alkalis must be given, and the general measures used which are applicable to the constitutional condition. If bronchitis depend on a gouty state, it will not yield to the ordinary treatment, but when its cause is recognised and the appropriate remedies are administered, the symptoms usually soon begin to improve.

In the cases of bronchitis which are connected with heart-disease, and especially with mitral regurgitation, digitalis is often of great value. By steadying the action of the heart it relieves the overloaded pulmonary veins, and thus directly diminishes the congestion of the mucous membrane, as mentioned in the paragraph relating to the pathology of the disease.

It is impossible in the scope of this article to refer specially to the treatment of bronchitic attacks arising from the various kinds of mechanical irritation. There is, however, one form of bronchitis which may be mentioned, viz. that connected with hay-fever, arising either from the inhalation of pollen, or caused by some peculiar atmospheric influence acting on a peculiar nervous system. It is very difficult of cure; no remedies seem to have any particular influence over it, and it is usually only to be relieved by removing the patient from the exciting cause of the affection. In the treatment of bronchitis depending on constitutional syphilis, the appropriate measures for that affection must be resorted to.

2. Chronic Inflammation—Chronic Bronchitis—Chronic Bronchial Catarrh.

DEFINITION.—A chronic inflammation of the bronchial tubes.

ÆTIOLOGY.—Chronic bronchitis very frequently results from repeated attacks of the acute disease, but it may be chronic from the beginning. Emphysema of the lungs, dilated bronchi, and tuber-

cular infection are causes of the complaint; as are also various forms of heart-disease, and some other diseases, such as gout. The prolonged inhalation of slightly irritating particles gives rise to chronic bronchitis; and it is also met with in connection with chronic alcoholism. It is most common among the old.

ANATOMICAL CHARACTERS.—The bronchial mucous membrane is discoloured, being of a dull-red tint, greyish, or brownish. The discolouration is usually partial, but sometimes general. There is swelling and increased firmness of the mucous membrane, and the sub-mucous tissue in old-standing cases becomes infiltrated and indurated. The fibrous tissue is increased; the cartilages in the larger tubes are sometimes calcareous; and there is generally more or less emphysema of the lungs.

SYMPTOMS.—The symptoms of chronic bronchitis vary greatly in different cases. They resemble in kind those of the acute affection. There is cough, expectoration, pain, soreness or uneasiness behind the sternum, with more or less dyspnoea. The constitutional symptoms may be very slight, scarcely any effect on the general health being apparent; or they may be very severe. Three forms of chronic bronchitis are recognised clinically:—(1) that which includes the ordinary cases of the disease, varying much in severity; (2) that characterised by excessive secretion—*bronchorrhœa*; and (3) that form which is called *dry catarrh*.

1. In the first form of chronic bronchitis the cough is at first slight, perhaps only occurring during the winter, being altogether absent in the summer. After a time the attacks become more frequent, and at last the patient is never free from the affection, which is aggravated at times. The cough in such cases is more or less severe, but usually most so in the morning. It is often paroxysmal, and sometimes very violent. The expectoration in some cases is scanty, viscid, and difficult to discharge, in others, especially old-standing cases, it is copious and easy. The sputa vary much both in appearance and quantity. They may be yellowish-white, muco-purulent, or more decidedly purulent, of a greenish-yellow or bright or dark green colour; they are but little aerated, sometimes not at all, so that they sink in water; at times they are nummulated and quite opaque. In some cases the expectoration is fetid, constituting the form of the disease denominated 'fetid bronchitis,' the odour resulting either from sloughing of minute portions of the mucous membrane, or from chemical changes taking place in the sputa. Occasionally streaks of blood are met with. Microscopically the sputa are found to consist of epithelium, pus-cells, and granular matter, with at times blood-corpuscles.

The constitution does not suffer much in mild attacks, but when chronic bronchitis is permanent and general, the system at large sympathises more or less severely: the appetite fails, sleep is disturbed by the cough, emaciation sets in and sometimes becomes marked, but it does not proceed beyond a certain point, unlike that of phthisis, which is usually progressive. In all cases of chronic bronchitis there is great risk of an acute attack coming on, especially among the aged. These attacks are very dangerous, in consequence of the rapid extension of the disease throughout the lungs, and its asphyxiating character.

2. The second class of cases is characterised by

excessive secretion from the bronchial tubes—*bronchorrhœa*. This form is often met with in the old and feeble, and especially in cases of valvular disease of the heart. The cough is paroxysmal, and attended with the expectoration of a large quantity of thin watery glairy fluid, or of thick ropy gluey matter, like white of egg. The quantity expectorated is sometimes very large. This form of bronchitis may cause death somewhat suddenly by asphyxia. During the paroxysms of cough there is dyspnoea, but at other times it is absent, except when heart-disease exists. The constitution suffers little, and the flux seems sometimes to be beneficial in cases of obstructive cardiac disease.

3. The third variety, or '*catarrhe sec.*' is characterised by very troublesome cough, oppression of breathing, tightness of the chest, and sometimes severe dyspnoea. Expectoration is either absent or very scanty, the sputa consisting of small masses of tough, viscid, semi-transparent mucus. There is usually no febrile disturbance. The disease is met with in gouty people, and is often associated with emphysema of the lungs.

PHYSICAL SIGNS.—Inspection reveals nothing abnormal in the form or size of the chest, unless emphysema of the lungs is present. The expansion in long-standing cases is usually deficient; the chest being raised more than in health. Expiration is often prolonged. Rhonchal fremitus may be felt more or less, depending on the state of the bronchial tubes. There is often increased resonance, from the presence of emphysema. The breath-sounds are more or less changed: they may be harsh and loud, and the expiration is prolonged in cases that have existed for a considerable period. The adventitious sounds vary: they are dry, coarse, moist, or bubbling according to the condition and contents of the tubes. Vocal resonance varies: it may be bronchophonic, normal, or deficient.

DIAGNOSIS.—There is usually but little difficulty in the diagnosis of chronic bronchitis. The affection is most likely to be confounded with phthisis, but the character and degree of the wasting, and the absence of increased temperature, of hæmoptysis, of tubercle-bacilli from the sputa, and of the physical signs of consolidation, will generally enable the practitioner to decide in favour of the less serious disease. The main difficulty lies in the diagnosis of cases where the bronchi are dilated; this will be referred to later on.

PROGNOSIS.—Although in itself not a dangerous malady, chronic bronchitis becomes so in consequence of the liability which exists to the occurrence of acute symptoms; when once established in middle or advanced age it is almost incurable. The complaint is further serious from its tendency to produce emphysema and dilatation of the bronchi. *Per se* it can scarcely ever be said to kill.

TREATMENT.—No case of chronic bronchitis can be successfully treated without due regard to the constitutional condition of the patient. In some cases it is impossible to cure the disease, and all efforts should be directed towards preventing its extension; alleviating the symptoms to which it gives rise; and warding off acute attacks. Attention must be paid to the state of the heart and kidneys; the duration of the affection; the age of the patient; the characters of the expectoration; the state of the lungs, as to the existence of emphysema or other morbid conditions; and the presence of gout or rheumatism. The functions of the liver must be

looked to: the administration of a few doses of blue pill with a saline aperient often gives great relief, and alters the character of the bronchial secretion. If the gouty diathesis is present, colchicum with alkalis and other remedies for gout, such as a course of Friedrichshall, Hunyadi, or Carlsbad waters, will prove of great service. If cardiac disease exist, whether in the form of valvular incompetence, or of weak, flabby, or dilated heart, digitalis combined with iron frequently produces marked benefit.

Chronic bronchitis, not dependent on any organic disease or constitutional condition, has a tendency to lower the health and to diminish strength, and therefore the various tonics may often be given with great benefit. Of these the most useful are quinine, the preparations of iron, and those of zinc. Cod-liver oil is also very valuable in some cases where there is much wasting. The cases of bronchitis marked by excessive secretion are generally best treated by tonics; while those in which the secretion is slight—cases of ‘dry catarrh’—being often associated with a gouty condition of the system, are more amenable to the use of colchicum, the alkalis, iodide of potassium, and mineral waters.

In what may be called the symptomatic treatment of the affection, the various expectorants are useful—carbonate of ammonium, ipecacuanha, squill, cascarrilla, senega, chloroform, &c., and these may often be beneficially combined with some form of tonic. In many cases of chronic bronchitis the expectorating power is diminished, and stimulating expectorants are of great service. Much caution must be exercised in the administration of opiates and other narcotics or sedatives. When, however, the mucous membrane is very irritable, and when there is but little secretion, with a troublesome cough, these remedies are indicated. Opium is of great value, and chloral hydrate is also very useful, as well as, in some cases, henbane and hydrocyanic acid, or, whenever spasm is present, stramonium, lobelia, the ethers, and cannabis indica. Inhalations are sometimes very beneficial, as of the vapour of warm water, iodine, creasote, and other substances. The inhalation of creasote is especially valuable if the expectoration is fetid.

Counter-irritation is one of the most important means we possess of relieving chronic bronchitis. The irritation should not be excessive, but should be long-continued. The application of iodine over a large surface of the chest, so as to keep up a constant slight inflammation of the skin, is perhaps the best that can be used; but other irritants may be tried, such as sinapisms, or the various stimulating liniments.

The general management of the patient is most important. A mild climate should, if possible, be chosen in the winter. The patient should live as far as possible in an atmosphere which is mild and dry. Although some cases are benefited by a moist and warm atmosphere, the majority of cases of chronic bronchitis do better in a drier one. The skin must be carefully looked to, its action should be well maintained, and warm clothing always worn. A moderate amount of some alcoholic stimulant is generally desirable; and the food should be nutritious and of easy digestion. Relief will often be found from wearing a respirator.

3. Plastic Bronchitis.—This is a rare form of disease, and of its particular causes nothing is known. It is perhaps connected with some peculiar diathesis. It may occur in either sex, and at any period of life,

but is most frequent in those who are of a tubercular constitution. It has been known, however, to attack persons of apparently healthy frame and in the enjoyment of robust health.

ANATOMICAL CHARACTERS.—Plastic bronchitis is anatomically characterised by the formation of concretions in the bronchial tubes. These concretions consist of fibrinous exudation from the mucous membrane; they form casts of the tubes, and are expectorated. These casts are either solid or hollow, and on examination are always found to consist of concentric laminae. They are, for the most part, poured out into the finer bronchial tubes, sometimes, however, into the larger ones, but never into the trachea. The casts are of a whitish colour, but they are often stained with blood. Microscopically they consist of an amorphous or fibrillated material, with leucocytes, granular matter, and oil-globules.

SYMPTOMS.—This disease is essentially chronic, but it has been met with as an acute affection in children. At the times when the casts of the tubes are expelled, exacerbations occur, the patient being attacked with pain and a sense of constriction across the chest, dyspnoea, and an irritating cough. After a time, varying from some hours to a few days, the dyspnoea becomes very urgent, and the cough very severe; then, after a paroxysm of coughing, it is found that the patient has expectorated some solid material, either with or without blood, usually intermixed with ordinary bronchitic sputa. The dyspnoea and cough now subside, to recur after an interval of a few hours or longer. This disease may last for weeks, months, or even years, marked from time to time by severe accessions, and relieved by the expulsion of further concretions. The matter expelled is often in small masses, but at times casts of bronchial tubes with several ramifications are expectorated. The disease may recur at intervals for many years; the general health in such cases does not seem to suffer, the breathing during the intervals being unaffected. There is, in some instances, an absence of febrile symptoms during the attack, while in others the fever is more marked. With the general symptoms are combined the *physical signs*. These are somewhat peculiar. The bronchial tubes being obstructed, portions of lung are deprived of air; the breath-sounds are therefore faint or absent. There may be dulness more or less complete on percussion, from collapse of the lung-substance, or, as occurs in some cases, from localised pneumonia. Asphyxia may be threatened if a large tube is blocked up.

DIAGNOSIS.—The diagnosis of this affection turns on the peculiarity of the expectorated matters. Doubtless the disease may be mistaken for ordinary bronchitis or pneumonia; but when once the fibrinous casts of the tubes are observed in the sputa, the nature of the case becomes clear.

PROGNOSIS, DURATION, TERMINATION, AND MORTALITY.—The prognosis, if the disease is uncomplicated, is favourable; but there is a great liability to recurrence. The complaint may last for many years, and may terminate in complete recovery. A fatal result generally depends on the presence of some other organic disease, such as phthisis or pneumonia.

TREATMENT.—But little can be advanced as to the value of any special treatment for this affection. Iodide of potassium is said to have been employed with success. The chief object should be to maintain the general health by hygienic measures, and the

exhibition of tonics, such as iron, quinine, and cod-liver oil, especially if there be any tubercular taint. During the exacerbations the administration of ammonia and the use of inhalations should be resorted to, and the general principles on which ordinary bronchitis is treated should be carried out.

4. Dilatation—Bronchiectasis.—This is a rare disease, which arises as a secondary affection. It is often associated with serious pulmonary mischief, and is at times difficult of diagnosis. There are two forms of bronchiectasis, namely, *general or fusiform dilatation*; and *saccular or ampullary dilatation*.

(1) The *general* or uniform bronchiectasis consists in a cylindrical dilatation of one or more of the tubes throughout a considerable portion of their extent. The tubes are evenly widened for the most part, and the dilatations end abruptly.

(2) The *saccular* form of bronchiectasis consists of a globular dilatation of a tube at one point, or at several points. The dilatations vary in size, being from half an inch to an inch or more in diameter. On the tracheal side they usually communicate with a slightly enlarged bronchial tube, while on the peripheral side the continuity of the tube is almost or entirely lost from narrowing or actual obliteration. Sometimes the cavities communicate with one another. The two forms of bronchiectasis often co-exist.

The walls of the dilatations undergo changes in the course of the disease. The mucous membrane becomes granular, swollen, and congested; while at a later stage it presents a velvety or villous appearance, and in some cases there is even ulceration with superficial necrosis. The muscular and elastic coats become atrophied, and, coincidently with this, dilatation increases. At times the wasting of these coats is partial; some portions of the walls retaining their natural volume, and forming bands or ridges elevated above the surrounding membrane. The dilated tubes occasionally present an appearance of hypertrophy; the walls are thickened, but the thickening depends on changes which have taken place in the mucous membrane. The cartilages resist the destructive metamorphoses longer than the other structures, but they sometimes partake of them. The contents of the tubes may be either muco-pus, or pus; and casts of the minute bronchi are met with. At times the contents are very foetid, and sometimes contain fragments of pulmonary tissue. It is said that the contents may become calcareous.

Dilatation of the bronchi may be unattended by any change in the surrounding lung-tissue, but, generally speaking, condensation of the latter takes place, as the result either of pressure or of chronic pneumonia. In some instances the tissue forms an abscess, in the centre of which the walls of the bronchus are found, while in others the walls of the bronchi and the surrounding tissue are destroyed by gangrenous inflammation. It is generally not difficult to distinguish between a phthisical cavity and a dilated bronchus. The latter is not characterised by the broken irregular surface which usually exists in the former; its shape is generally more regular; and it is usually continuous with bronchial tubes. The surrounding lung-tissue has no tubercular infiltration.

The *mechanism* of bronchiectasis has occupied much attention. It is probable that the elastic and muscular fibres lose their elasticity and contractility as the result of chronic inflammation, and thus yield

to the distending influence of coughing. When once a dilatation is produced, accumulation of the secretions takes place, which tends further to increase the dilatation.

SYMPTOMS.—The symptoms of bronchiectasis are those of chronic bronchitis aggravated in some important respects. The cough is frequent and paroxysmal. The expectoration is very abundant, very purulent, and, when the disease has lasted some time, very foetid. The expectoration of large quantities of purulent secretion at longer or shorter intervals is highly characteristic of this disease. The breath also becomes foetid. Hæmoptysis is occasionally met with, even to a considerable extent. There is more wasting than in ordinary bronchitis, and the blood is more imperfectly aerated. Night-sweats are not uncommon. In fact, the general symptoms approach those of phthisis. The digestive functions are usually not much impaired.

PHYSICAL SIGNS.—The movement of expansion is diminished in bronchiectasis, while that of expiration is prolonged. Over the affected portions of the lung there may be slight retraction. Vocal fremitus is increased, and rhonchal fremitus is sometimes well marked. The percussion note is altered. If a dilated tube is surrounded by condensed lung-tissue, or is full of secretion, there is dulness on percussion; but if it is situated near the surface and empty, some degree of tubular resonance may exist. Cracked-pot sound may be, at times, elicited. The respiratory sounds are harsh, or loudly bronchial with a more or less blowing character, and they may be distinctly cavernous. Vocal resonance is often greatly increased. The pulse becomes rapid in the later stages. The temperature rarely if ever reaches the height that it does in phthisis with cavities, and the daily oscillations are not so marked.

DIAGNOSIS.—The main difficulty as regards diagnosis is in the differentiation of certain cases of phthisis with cavities from bronchiectasis with large globular dilatations. The points to be relied on are that in the latter disease the morbid physical signs are usually met with at the middle and lower parts of the lungs, while in ordinary phthisis they are found at the apex; that the temperature differs in the two affections as mentioned above; that emaciation and night-sweats are not so marked in bronchiectasis; and that, if cases are watched, there is usually observed a progressive advance of symptoms in phthisis, while in bronchiectasis the symptoms may remain stationary. In phthisis signs of consolidation precede those of cavities, while they follow them in bronchiectasis, and in the latter disease tubercle-bacilli are absent from the sputa. Bronchial dilatations and tubercular cavities have been found in the same lung. The foetor of the breath and sputa in bronchiectasis may cause a suspicion that gangrene of the lung is present; but the general symptoms will usually enable the practitioner to differentiate between the two affections.

PROGNOSIS.—Bronchial dilatation is probably never cured. It may last for years.

TREATMENT.—The treatment of bronchiectasis must be that of chronic bronchitis with the use of such measures as are applicable to wasting diseases in general. The foetor of the breath is best relieved by the inhalation of creasote, or some similar antiseptic. The disease has, in some cases, been treated successfully by incision and drainage.

5. Narrowing or Obstruction.—Narrowing or obstruction of the bronchial tubes is by no

means uncommon, and may depend on intrinsic or extrinsic causes. Complete obliteration of a tube is sometimes found in connection with bronchiectasis, immediately beyond a globular dilatation.

ÆTIOLOGY.—The *intrinsic* causes of obstruction are a thickening of the mucous membrane resulting from bronchitis; the cicatrization of tertiary syphilitic ulcers; the retention of viscid secretions; the exudation of plastic material into the interior of the tubes; and the deposition therein of tubercle or cancer.

Among the principal *extrinsic* causes are the pressure of adjacent tuberculous or cancerous deposits; the contraction of plastic matter exuded into the tissues surrounding the tubes; solid formations in the pleura; enlarged bronchial glands; and aneurysmal and other thoracic tumours.

Obstruction is most frequently met with in the smaller tubes, but the pressure of thoracic tumours not infrequently causes obstruction, or even obliteration of a main bronchus, which occasionally—as in the case of aneurysms—becomes perforated.

SYMPTOMS.—If a large bronchial tube become suddenly and greatly obstructed, dyspnoea of an urgent character sets in, and death from asphyxia may speedily result, unless the obstruction be removed. When the obstruction is on a smaller scale, being confined to the smaller tubes, or when a large tube suffers only from slow, gradually increasing obstruction, the symptoms are by no means urgent for a time, and slight dyspnoea, sometimes accompanied by stridor, is the most marked feature.

PHYSICAL SIGNS.—Complete obstruction of a bronchial tube invariably leads to collapse of the portions of the lung to which the tube is distributed, and thus an entire lung may collapse if its main bronchus be obliterated. Where partial collapse is produced, emphysema of the neighbouring lung-tissue commonly follows, and if one lung become collapsed, the opposite lung becomes enlarged and emphysematous. The existence of collapsed lung gives rise to dullness on percussion over the affected part, unless this be situated away from the chest-walls, or masked by the presence of emphysema. Further, obstruction of the bronchi causes a weakness or deficiency of the respiratory sounds, with a prolonged expiratory murmur, attended at times by sonorous and sibilant rhonchi. Over the collapsed portion of the lung, or over portions of the lung supplied by a tube which has become completely obstructed, the breath-sounds are absent. Deficiency or absence of vocal vibration is another physical sign of obstructed bronchial tubes.

TREATMENT.—The treatment of obstruction of the bronchi must depend on the nature of its cause. The chief interest of the affection arises from the means of diagnosis of thoracic tumours which it may afford.

6. Cancer.—Cancer of the bronchial tubes occurring independently of cancer in the lungs, or mediastina, is probably never seen; but cancerous matter has been found in the tubes: (1) in cases where the lungs have been infiltrated with a similar deposit; (2) where a cancerous tumour connected with the root of a lung has perforated a tube; and (3) in some cases of cancerous disease of the lung, a tumour of a similar nature being found connected with the mucous membrane of a tube.

(4) Cancerous matter has also been found *in transitu* in a tube, having been detached from a cancerous mass.

BRONCHIAL GLANDS, Diseases of.—

SYNON.: Fr. *Adénopathie Trachéobronchique*; Ger. *Krankheiten der Bronchialdrüsen*.

GENERAL ANATOMY.—The bronchial glands, about twenty-five in number, receive the lymphatic vessels from the lungs, bronchial tubes, and visceral pleura. Some, often called the *tracheal glands*, are situated around the lower end of the trachea; others, including the largest of all, lie immediately below the tracheal bifurcation, while smaller ones are placed along the two main bronchi. In addition, a number of still smaller glands, about forty on the right side and thirty on the left, lie actually embedded in the lung substance near its 'root,' between the divisions of each main bronchus to the third or fourth ramification; these are sometimes spoken of separately as the *pulmonary glands*.

While anatomically the term 'bronchial' is restricted to these groups, it frequently happens that when they are diseased others in the thorax are involved also, especially the *superior mediastinal or cardiac glands*, an important group situated in the upper part of the interpleural space, in the neighbourhood of the arch of the aorta and continuous below with the bronchial glands proper. Disease of this group may cause some of the symptoms and physical signs commonly attributed to enlargement of the bronchial glands only.

It is also of importance to recollect that some lymphatic vessels from the posterior mediastinal glands pass into the bronchial group. As the former receive lymphatics from the diaphragm, a channel thus exists whereby infection, as in tuberculosis, may be conveyed from the abdomen to the bronchial glands. These glands, especially if those of the superior mediastinum be included, are in close relation to a large number of important structures: the trachea and main bronchi; the pulmonary vessels; the innominate veins and superior vena cava; the arch of the aorta; the vagus nerves and their recurrent branches—especially on the left side; the pericardium; the œsophagus; and the adjacent nerve-plexuses. The bronchial glands are relatively larger in children than in adults, the largest being about the size of a small almond. In infancy they are of a pale red or pinkish colour, but in a few years become studded with dark spots, and in later life, especially in town-dwellers, are often almost black from inhaled particles of carbon. As the largest glands, and those most liable to become considerably hypertrophied, are grouped round the lower end of the trachea, it is important to bear in mind that the tracheal bifurcation corresponds on the surface with the junction of the manubrium and body of the sternum in front and with the fourth dorsal spine behind.

MORBID ANATOMY AND PATHOLOGY.—The lymphatic glands throughout the body are most active in childhood; greater functional activity involves greater proneness to disease, at least to inflammatory processes of all kinds; and in accordance with this general rule we find that diseases of the bronchial glands are met with especially in children.

The chief morbid processes affecting the glands are the following :

1. *Lymphadenoma*.—In this disease the bronchial glands, along with the other groups in the thorax, are often involved, though usually after those situated externally. The enlargement may be very great. In the spleno-lymphatic or rarer form of lymphadenoma the bronchial glands frequently present a moderate degree of hypertrophy. See LYMPHADENOMA.

2. *Mediastinal growths*.—Lympho-sarcoma when commencing in the thorax usually starts in the bronchial glands and may give rise to an extreme degree of enlargement. Carcinomatous deposits, nearly always secondary, also occur.

3. *Syphilis*.—In both the secondary and tertiary stages, this often causes swelling of the lymphatic glands generally, in which the bronchial glands participate. The latter are most hypertrophied in cases of tertiary syphilis affecting the lungs, in which enlargement of the glands up to the size of a pigeon's egg has been recorded.

4. *Congestion and Inflammation*.—In practically all persons, but most of all in children, dying from acute bronchitis, pneumonia, or broncho-pneumonia, the bronchial glands are found swollen, hyperæmic, and somewhat softer than normal; in extreme cases they may be pale from excessive cell-proliferation. This, of course, is merely an example of the general law that acute inflammation in any part of the body tends to cause swelling of the associated lymphatic glands. The enlargement is most marked in cases of measles and whooping cough, especially in the large gland placed exactly in the tracheal bifurcation. The peculiar cough of pertussis has been attributed to the pressure of this and of other glands, but, inasmuch as an equal or greater degree of swelling may be met with in cases in which there has been no whoop, this explanation can hardly be regarded as adequate. The mistake has probably arisen from the fact that enlarged bronchial glands may give rise to a spasmodic cough which more or less resembles that of pertussis. See WHOOPING COUGH.

5. *Chronic Hypertrophy*.—Chronic hypertrophy of the bronchial glands is apt to be a sequel of the inflammatory condition just described, if this is prolonged by repeated catarrhs or by chronic pulmonary disease. Its chief importance lies in the fact that it undoubtedly predisposes, at least in early life, to tubercular lesions in the glands. The course of events is probably precisely similar to that occurring in the cervical glands, in which a chronic adenitis is maintained by some simple irritant, such as chronically enlarged tonsils, or a carious tooth, until the chance arrest of tubercle-bacilli in these unhealthy glands results in definite tuberculosis.

6. *Suppuration*.—Suppuration of the bronchial glands is a rare event, and the conditions under which it occurs are not very clear. Probably it is most frequently associated with the presence of tuberculosis; very rarely it may be secondary to acute pneumonia.

7. *Caseation*.—Caseation of the bronchial glands is found in a large proportion of autopsies upon cases of ordinary pulmonary tuberculosis. There is no need to describe the process in detail; small scattered milium granulations appear, enlarge, become caseous, and gradually coalesce, until

entire glands are converted into caseous masses, generally—though not necessarily—with considerable enlargement. In adults this is a purely secondary process and rarely a matter of clinical importance, any symptoms to which it may give rise being overshadowed by those due to the primary lung-disease.

Caseation of the bronchial glands in children is, however, of far greater importance, and three special features call for notice.

(a) *Its great frequency*.—In children who have died with tubercular disease in any part of the body, the bronchial glands are usually affected, just as in adults the lungs rarely escape; and as statistics from the *post-mortem* rooms of the Children's Hospitals in London prove that fully one-third of the cases show evidence of tuberculosis, it is easy to see how extremely common caseation of these glands must be. Out of 120 autopsies on children presenting tubercular lesions, the writer found caseation of the bronchial glands in 96 (80 per cent.), and a more careful examination of some of the remaining cases would probably have still further increased this number. Some observers state that caseation of the mesenteric is more frequent than of the bronchial glands, but this certainly does not conform with the experience of the London Hospitals.

(b) *Its occurrence independently of lung disease*.—Caseation of the glands is frequently present when no pulmonary lesion whatever is to be found: a complete contrast to what usually obtains in adults. This primary involvement of the glands may conceivably occur in four different ways, of which the first is probably the most common.

(i) It is now definitely recognised that tubercle-bacilli may pass through the pulmonary alveoli without producing any lesion, and subsequently lodge in the glands, where they give rise to characteristic changes. Unquestionably a similar primary infection of the mesenteric glands may be set up by bacilli which have passed through the intestinal mucous membrane. (ii) The bacilli may enter by the intestine and infect the bronchial glands indirectly *via* the posterior mediastinal glands, as previously described. (iii) The bacilli may enter by the tonsils and pass *via* the cervical and tracheal to the bronchial group of glands. (iv) Possibly a few bacilli having gained access to the blood, no matter how, may lodge and develop in the bronchial glands, merely because these happen to present a suitable soil, just as an injury to a joint under similar conditions may be followed by tubercular arthritis. In this case the lodgment of the bacilli is facilitated by the glands being in a condition of chronic engorgement and hypertrophy, with stagnation in the lymph-channels passing through them. Hence it is that measles, pertussis, and any chronic catarrhal condition of the bronchial tubes or lungs in children so greatly predispose to the development of tubercular changes in the bronchial glands.

(c) *Its varied and serious secondary consequences*.—The most important are the following:—

(i) *Ulceration into adjacent parts*.—Around the bronchial glands, as around others, when caseous, some periadenitis is often set up, leading to adhesions between them and neighbouring structures. At the same time the caseous material may gradually soften and eventually ulcerate through into adjacent parts. Naturally, from the position of

the glands, perforation occurs most frequently into the trachea, near its bifurcation, or into one of the main bronchi, commonly the right. The caseous matter is then either gradually expectorated or else sets up a diffuse broncho-pneumonia or tuberculosis. Occasionally the gland enters the trachea suddenly *en bloc* and causes rapid asphyxia and sudden death—a somewhat rare event in childhood. The glands may also ulcerate into the oesophagus, and sometimes a communication is established between the latter and the air-passages, diffuse gangrene of the lungs resulting. In fact gangrenous abscess of the lung in children is more frequently produced by caseous bronchial glands than by any other cause except a foreign body. Very rarely the glands may ulcerate into the pericardium, the pulmonary artery, the aorta, or the mediastinum; in the latter case giving rise to a mediastinal abscess, which may point externally. It has already been suggested that some of the recorded cases of suppuration of the bronchial glands may have been primarily instances of caseation.

(ii) *Secondary extension to the lungs*.—In young children the most usual origin of pulmonary tuberculosis seems to be by extension from caseous bronchial glands. In these cases there is advanced caseation of the bronchial glands, especially of the so-called pulmonary group which lie embedded in the lung-substance. They soften and discharge their contents into the bronchi, leaving small cavities; the process being just the same as the ulceration into the trachea already described, and, as in the latter, the inhalation of the infective products into the bronchioles may lead to an acute diffuse tuberculosis of the lung. More commonly however the disease advances slowly into the adjacent pulmonary tissue, until at last the lung, or it may be one lobe, for some distance round its root, is converted into a caseous mass riddled by small cavities; further out isolated caseous nodules are met with, evidently of more recent formation, while the apex and peripheral parts of the lung may be healthy or contain only scattered tubercles. In a series of autopsies every intermediate step can be traced, from the commencement in the glands onwards to complete destruction of the lung.

The difficulties in diagnosis which such cases may present, especially in the earlier stages, are obvious, and are increased by the fact that occasionally narrowing of a main bronchus by enlarged glands may lead to bronchiectatic changes in the lung behind the obstruction.

(iii) *General blood-infection*.—A softening mass of caseated tubercles is always liable, by means of the blood-stream, especially in children, to give rise to acute general miliary tuberculosis. While in adults the infective tubercular focus is generally found in the lung, in children it is usually situated in the bronchial glands, one or more of which are caseous and softened. So far as the writer's personal observations go, in 44 autopsies upon cases of tubercular meningitis in children, specially examined with the object of determining the primary focus of infection, the bronchial glands appeared to be the primarily affected part in more than half the number.

(iv) *Obsolescence*.—In a large number of cases, fortunately, caseous bronchial glands dry up, and become surrounded by a firm fibrous capsule, while the caseous contents often undergo calcification—similar changes to those which may occur in

other tuberculous organs. Such glands may remain quiescent for an indefinite number of years, though probably still potentially capable of fresh activity.

Of the above-mentioned causes of enlargement of the bronchial glands the first two are described elsewhere (*see* LYMPHADENOMA; AND MEDIASTINUM, Diseases of); the subsequent parts of this article will therefore deal mainly with caseation of the glands and non-infective enlargement.

SYMPTOMS.—(a) *General*.—Active tuberculosis in the bronchial glands, as in any other part, causes fever of a hectic type, with wasting and general malaise. When the disease is no longer active symptoms will of course subside.

(b) *Local*.—Very considerable enlargement of the glands may exist without giving rise to any clinical phenomena, and it is only in extreme cases that any of the symptoms to be presently enumerated are met with. Symptoms are most typical when the enlargement is due to lymphadenoma or lympho-sarcoma. *See* LYMPHADENOMA.

1. *Cough*.—This is the most frequent symptom. It varies in character. Its occasional resemblance to that characteristic of pertussis has already been referred to. When due to disease of the glands, the crowing inspirations are less marked, the paroxysms shorter, the invasion and period of accession of the cough less regular in their sequence, while the fever and emaciation are more distinct.

2. *Expectoration*.—Some expectoration of mucus from slight bronchial catarrh is not uncommon. It is likely to be abundant should the enlarged glands compress the pulmonary veins and so lead to passive congestion and oedema of the lungs. When softening glands ulcerate through into the trachea, thick pus-like expectoration may be coughed up, and the case may even be mistaken for an empyema which has ruptured into the lung.

3. *Hæmoptysis*.—There may be slight, severe, or even fatal hæmoptysis. This may be due to ulceration into the air-passages, to erosion of vessels in the lung, or to congestion from glands compressing the pulmonary veins. In a few cases a large vessel has been perforated as well as the trachea or main bronchus, so that profuse hæmorrhage has taken place directly into the latter.

4. *Pain*.—In a considerable number of cases pain is complained of and is usually referred to the back, at the level of the fourth and fifth dorsal vertebrae, occasionally to the front, behind the upper end of the sternum. Sometimes there is associated tenderness.

5. *Dyspnœa and stridor* may be caused by direct pressure of the enlarged glands on the trachea or one of the main bronchi. Dyspnœa may also be brought about indirectly by pressure on the vagus or recurrent laryngeal nerves, causing laryngeal spasm or palsy, perhaps with hoarseness or aphonia.

The question naturally arises here what relationship, if any, exists between enlargement of the bronchial glands and asthma. Some writers go so far as to state that most cases of 'asthma' in early life are due to direct pressure of enlarged glands upon the air-passages. They may indeed, as just explained, cause dyspnœa in this way, and such dyspnœa may be more or less paroxysmal in character; or they may indirectly, by pressure on the vagus nerve, give rise to attacks simulating asthma; but dyspnœa so produced has no more claim to the name of asthma than has that due to the pressure of an aneurysm. True asthma is essentially a neurosis: the actual attack

may be excited by a great number of causes, and it is possible, even probable, that one of these causes in a predisposed subject may be enlarged bronchial glands, adherent to or pressing upon and irritating (without necessarily narrowing) the walls of the trachea or bronchi. Therefore when in any particular case of asthma, especially a child, we are trying to discover the actual exciting cause of the attacks, the possibility of enlargement of the bronchial glands should not be overlooked. They may not be so common a cause as gastric irritation or bronchial catarrh, but at any rate they should not be ignored, when such remote factors as nasal polypi, uterine disorders, or even emotions are looked upon as conceivable excitants of the attacks.

6. *Dysphagia*.—Occasionally dysphagia is produced by compression of the œsophagus.

7. *Vomiting*.—Vomiting has been attributed to pressure on the vagus nerves, but is perhaps more often due to the severity of the cough.

PHYSICAL SIGNS.—Considerable enlargement of the bronchial glands may exist without giving rise to any definite physical signs. Those which may be met with are the following.—1. *Inspection and Palpation*.—Signs of venous congestion are not uncommon from pressure of the glands upon the innominate veins or superior vena cava. There is often marked visibility of the cutaneous veins over the upper part of the chest, especially about the manubrium sterni, and sometimes actual puffiness or œdema of the face and neck. Obstruction of one bronchus may lead to deficient expansion or to actual flattening of the affected side; general recession of the soft parts of the chest-wall may be caused by tracheal obstruction.

2. *Percussion*.—The enlargement of the glands may be sufficient to give rise to deficient resonance or actual dulness; this is most frequently present over the manubrium and at the inner end of the first and second intercostal spaces, also occasionally in the interscapular region, at the level of the fourth or fifth dorsal vertebrae, at any rate in cases of enlargement from lymphadenoma or new-growth, but very rarely when the glands are simply caseous.

3. *Auscultation*.—Breathing may be bronchial over the dull area. If a main bronchus be compressed the breath-sounds will be weak over the corresponding lung and perhaps proportionately loud over the other lung. Eustace Smith lays much stress on the significance of a venous hum heard over the manubrium when the head is thrown back as far as possible; he attributes it to the enlarged glands compressing the left innominate vein, the retraction of the head tilting forward the lower end of the trachea and with it the glands. Undoubtedly this sign is frequently present in children, but whether it always indicates glandular enlargement is as yet unsettled.

DIAGNOSIS.—Various diseases with which enlargement of the bronchial glands may be confused have already been referred to. When the enlargement is extreme the diagnosis is an easy matter, for the symptoms and the physical signs may alike be characteristic. The really important question is what are the points to which attention should be directed in endeavouring to arrive at a diagnosis in a doubtful case, when, as in tubercular disease, the enlargement is not great and yet may be important to recognise. Not only may physical signs and local symptoms alike be absent, even when the glands are extensively diseased, but nearly all the

symptoms and some of the physical signs before enumerated may be due to lung-disease alone. Now we have seen that such disease is very apt to follow caseation of the glands, and although when this has taken place the condition of the latter becomes of secondary importance, it is important to be able to recognise that they are enlarged before the serious consequences have supervened.

No one sign or symptom is ever pathognomonic, but a very suggestive combination of conditions is (a) enlargement of cutaneous veins over the top of the chest, (b) some deficiency of resonance over or on either side of the manubrium, and (c) a venous hum in the same position when the head is retracted; especially if these occur in a thin delicate-looking child, suffering from a cough, for which no cause can be detected in the throat or lungs, and from slight intermittent evening pyrexia without assignable cause. Enlargement of glands elsewhere, especially in the neck, may afford further help in diagnosis. Skiagraphy is unlikely to be of much service in cases where other indications are absent, but where they establish a probability, it may afford confirmatory evidence.

In children it is very common to meet with slight deficiency of resonance just to the left of the manubrium, without any other indication of disease, and the presence of the thymus as a cause of impairment must not be forgotten. When at its maximum development, at two years of age, this organ occupies the superior mediastinum behind the sternum as far as the fourth rib-cartilage; its two lobes are generally of unequal size, sometimes the right and sometimes the left being the larger.

Bearing in mind the large number of children who, as shown by subsequent *post-mortem* examination, suffer from tuberculosis of the bronchial glands, and the great probability that this has caused, at some time or other, fever and malaise, we should make it a rule in children with definite emaciation or persistent unexplained evening pyrexia, not to be content with a diagnosis of gastro-intestinal catarrh, but to recollect that the symptoms may be due to caseation of the bronchial glands, especially if the child has recently suffered from measles, pertussis, or bronchitis.

PROGNOSIS.—Calcified glands may remain perfectly quiescent for the remainder of the patient's life, especially if he is placed under favourable hygienic conditions. It is moreover probable that complete arrest may occur even when glands have ulcerated into the trachea or bronchi; but if tuberculosis once extend to the lungs a fatal result will probably ensue. At the best, however, a caseous mass in any part of the body is always to be regarded, like a chronic otorrhœa, as a potential source of danger. Tubercle-bacilli may retain their vitality in it for an indefinite period, and should anything occur to impair the general health, the enveloping fibrous capsule may break down, and either local or general tuberculosis follow.

TREATMENT.—This must be conducted on exactly the same general lines—climatic, hygienic, dietetic, and medicinal—as in dealing with tuberculosis in other parts of the body. It is especially for tuberculosis of the lymphatic glands in children that the watering-places on the north-east coast of Kent seem peculiarly suitable. Every effort must be made to improve the child's general health and nutrition and to check any tendency to catarrh of the respiratory passages, in order to allow of the

subsidence of the congestion and hyperplasia of the glands resulting from it; or, if caseation have occurred, to place the patient in the best possible position for the encapsulation and calcification which offer the only prospect of an even imperfect cure. If this result follow, it still remains equally important to maintain the health at as high a level as possible, remembering that any failure in this may result in recrudescence and extension of the local disease. Cod-liver oil and syrup of the iodide of iron or tincture of iodine internally, with local counter-irritation by iodine externally, are to be especially recommended. Should there be the least suspicion that the glandular enlargement is of syphilitic origin, a suitable line of treatment must of course be adopted. See CLIMATE, Treatment of Disease by.

J. WALTER CARR.

BRONCHIECTASIS.—See BRONCHI, Diseases of.

BRONCHOCELE (βρόγχος, the throat; and κήλη, a tumour).—A synonym for goitre. See GOÏTRE.

BRONCHOPHONY (βρόγχος, the throat; and φωνή, the voice).—The resonance of the voice, as normally heard on auscultation over those parts of the chest which correspond with the main bronchi, and, in certain morbid conditions, beyond these situations. See PHYSICAL EXAMINATION.

BRONCHO-PNEUMONIA.—A synonym for catarrhal pneumonia. See LUNGS, Inflammation of.

BRONZED SKIN.—A term generally used to denote the peculiar discolouration of the skin associated with Addison's disease. See ADDISON'S Disease.

BROW-AGUE.—A synonym for frontal neuralgia, or tic-douloureux. See MALARIA; NEURALGIA; and TIC-DOULOUREUX.

BRUIT (Fr. *bruit*, a noise).—A word used to designate various abnormal sounds heard on auscultation, in connection with the heart or vascular system. See PHYSICAL EXAMINATION.

BUBO (Βουβών, the groin).—SYNON. : *Apostema inguinis*; *Dragoncelus*; Fr. *Bubon*; Ger. *Leistenbeule*.—Primarily, as synonyms show, a swelling of an *inguinal* gland, usually of venereal origin. The term is now practically limited (1) to glandular swellings secondary to chancres and chancroids (genital or extragenital), or to gonorrhoea; and (2) to glandular swellings, often inguinal, in 'bubonic' plague. See PLAGUE.

BUBO, VENEREAL.—DEFINITION.—An inflammatory swelling of one or more glands, usually inguinal, due either to chemical or to infective irritants absorbed from a primary venereal lesion, usually genital.

VARIETIES.—Buboes are divided into :—1. Simple bubo; 2. Chancroid or virulent bubo; and 3. Syphilitic bubo. The gland first affected is always that in most direct communication with the sore. When an acute inflammation is excited the irritant does not, as a rule, pass from the gland first affected to another more remote in the series. On the other hand, the more slowly acting irritant of

syphilis affects gland after gland of a group till all are involved.

Buboes occur most frequently on the side of the body occupied by the source of irritation; they may occur simultaneously on both sides, and may be even limited to the side opposite to the position of the exciting sore. When buboes form in both groins, there is usually a sore on each side or one at the mesial line, which infects lymphatics passing to each groin. When the gland affected is on the opposite side to the sore, there is an unusual distribution of the lymphatics. Bubo, including simple and virulent, occurs in about thirty per cent. of chancres; how often with urethritis and other lesser venereal affections is not known.

1. **Simple Bubo.**—This variety may be either non-suppurating or suppurating. In either case it may be caused by the introduction of pyogenic organisms into the lymphatics, whence they are conveyed to the glands; or it may be due to chemical irritants produced by organisms at the primary lesion. Simple venereal buboes are thus pathologically identical with cases of non-venereal lymphadenitis due to absorption of similar irritants from infected wounds, scratches, fissures, boils, herpetic and other erosions; for in this instance the venereal lesions—whether balanoposthitis, anterior urethritis (gonorrhoeal), chancroid or ulcerating chancre—merely serve as foci whence the above-named common irritants are absorbed. Whether the primary focus be non-venereal or venereal in origin, absorption from it and consequent suppuration of glands are much favoured by dirtiness of, and retention of discharge in contact with, the primary lesion.

It is important to remember that the inguinal glands receive their lymph-supply from the penis (a few deep vessels pass behind the pubic arch), scrotum, perineum, anus, skin of the buttock and of the lower abdomen, and in the female from the vulva. If the starting-point of the infection cannot be found upon the genitals, the other regions from which the glands are supplied must be carefully examined. It is possible that the infecting virus may be absorbed by the lymphatics without producing a sore on the surface (*bubon d'emblée* or primary bubo).

SYMPTOMS.—There are two forms of simple bubo :—1. Slight swelling and tenderness of one or more glands, ending in a few days by resolution. This occurs most frequently in urethritis, balanoposthitis, or simple chafings. In genuine chancroid the next and more serious form is most frequent. 2. Swelling, commonly of one, seldom of several glands; brawny thickening of the surrounding tissues (periadenitis); redness of the integuments; great tenderness and pain, especially when walking. In a few days this condition terminates either by abscess, the most frequent culmination, by gradual subsidence to the normal state, or by chronic induration of one or more glands. When the bubo suppurates, the matter, instead of pointing at once, may burrow in various directions, and burst through the skin at various spots, leaving very chronic sinuses. Occasionally, in a mass formed of many glands, abscess follows abscess and fresh sinuses undermine the skin. The patients are often in feeble health, and it is said that the glands have become tuberculous: bacteriological or even histological proof of this does not seem to have been given.

PROGNOSIS.—This form of bubo is seldom dangerous, but when chronic suppuration of several glands and burrowing occurs, it is very tedious and exhausting to the patient.

2. Black Chancroidal Bubo.—**Virulent Bubo.**—**ÆTIOLOGY.**—The exciting cause of lymphatic abscess secondary to chancroids is unknown and is likely to remain so until the cause of the chancroid is discovered. In some cases ordinary pyogenic organisms have been found; such have been included under the previous heading. In the majority of such abscesses which have been examined no specific organisms have been found, but it seems premature to conclude that the suppurative is due to a chemical irritant absorbed from the ulcer. The development of a bubo is favoured by exercise, unclean linen, and retention of discharge by scabbing or phimosis. Size and multiplicity of sores seem to have little effect. It is most common in the second to the fourth week, but may be almost simultaneous with the chancroid, or occur even after this has healed. It is much less common in women than in men. Perhaps 30 per cent. of hospital cases develop an abscess. The great majority of these run the course of a simple bubo; exceptionally, two or three days after incision, one proves itself chancroidal—in appearance and in inoculability. This form is never a consequence of gonorrhœa or of a true syphilitic chancre, but only of a chancroid. It may be generated in two ways: 1. by the infecting of a simple open bubo with chancroidal pus; and 2. by the entrance of the chancroidal virus into the lymphatics leading from the chancroid to the gland most directly connected with the sore. The first view is probably correct.

SYMPTOMS.—Chancroids being rarely extra-genital, buboes secondary to them, whether simple or virulent, are usually inguinal. Both varieties may occur elsewhere. At first the symptoms of specific bubo are those of acute abscess forming rapidly in and round a single gland. Thus far they differ nowise from those of simple bubo. Two or three days after bursting the simple suppurating cavity becomes a spreading ulcer, which rapidly destroys the skin and exposes the base of the cavity. A large amount of matter escapes; it is thin, yellowish-grey, or yellowish-red, with shreds of a chocolate colour floating in it.

The further progress varies. In the least severe variety the edges of the skin ulcerate irregularly for a short distance, then thicken and begin to granulate; the floor of the ulcer loses its unevenness and rises up to the level of the skin; and cicatrization follows. But commonly a much greater destruction of tissue is effected. The skin is eaten away into wide gaps; long channels form under it or dive deeply among the great vessels. In other cases the ulceration produces a large shallow sore. The contagious condition of these buboes often continues for weeks or months, so that consecutive inoculation of the skin is not infrequent. The characters of the fully formed virulent bubo are those of the chancre. The surface is greyish-brown, dug-out, 'worm-eaten'; the borders at some parts are thickened, everted, and pared away, at others sharply eroded or undermined and curled in. The matter is thin, shreddy, plentiful, reddish in colour, and inoculable. Like the chancre, the virulent bubo passes through periods of *extension*, *arrest*, and *repair*. The virulent, as well as the simple bubo, is liable to erysipelas and gangrenous sloughing.

The *duration* of virulent bubo for the reason stated is wholly indefinite—in a few cases ending in a week, in many cases lasting for months.

DIAGNOSIS.—The virulent bubo has in its early stage no distinguishing mark from the simple acute bubo. After it has become inoculated with the contagious matter it is distinguished from every other affection by the characters already described. Nevertheless, in some cases the signs of virulence are so feebly marked throughout that the diagnosis remains uncertain. This difficulty may be increased by the primary sore having healed before the suppurative of the bubo, or by its being hidden in some unusual position (urethra, anus).

PROGNOSIS.—This is not always grave. Virulent buboes often reach cicatrization in a few weeks, and meanwhile cause no serious inconvenience. On the other hand, if the patient have suffered from syphilis some years previously, or be in depressed health from alcoholism, diabetes, albuminuria, and the like, phagedæna may attack the ulcers, and thereby permanently cripple the patient, or even destroy life by hæmorrhage or sepsis.

3. Syphilitic bubo.—*Indolent multiple bubo; pléiade ganglionnaire.*—This enlargement of the group of lymphatic glands in nearest connection with the initial sore is an almost constant symptom of early syphilitic infection. In this it differs much from the bubo of chancre or gonorrhœa, in which affections the bubo is more often wanting than present. Three conditions have been noted to exist in patients in whom the enlargement of the glands could not be detected—namely: 1. Phagedæna of the sore. 2. Obesity; in such persons the lymphatic system as a rule is small. 3. Scantiness of the induration of the primary sore, the sore itself being ill-developed. But these exceptions are most rare. Fournier gives five instances only of absence of indolent multiple bubo in 265 cases of hard sore, accompanied by well-marked general syphilis (2 per cent.). In 176 similar cases noted by Berkeley Hill three had no apparent inguinal enlargement. One of the patients was a very fat man, and in another the initial sore was only slightly hardened. The enlargement of the glands is first perceived about eleven days after the induration of the sore, though probably the affection commences at the end of the incubation of the poison. In extremely rare instances enlargement is delayed until the third or fourth week after the induration of the sore. When patients acquire both a genital and extra-genital initial lesion simultaneously or nearly so, not only the glands of the groin, but also those of the extra-genital region are enlarged.

The seat of these buboes is, in all genital and perigenital cases, the inguinal glands. The glands of other regions—epitrochlear, axillary, sub-maxillary (sub-mental), cervical and nuchal (pre-auricular)—are all occasionally found primarily enlarged in extra-genital cases.

SYMPTOMS.—The glands are enlarged in both groins, those on the side of the sore being most affected. In a few cases the enlargement is limited to the glands situated on the same side of the body as that of the sore, and in rare instances to those of the side opposite to that of the sore. The enlargement affects first the gland nearest to the lesion, and then rapidly involves the other members of the group. The patient usually makes no complaint of the buboes. Each of the affected glands is found to be swollen, but is rarely larger than an almond or hazel-

nut ; it is of gristly hardness, insensitive to pressure, isolated from, and mobile among, its fellows, there being no periadenitis ; the skin over the glands is quite normal. Such glands are often spoken of as 'amygdaloid' or 'bullety.' The gland in most direct communication with the sore is most affected ; in rare exceptions only a single gland is enlarged. Great enlargement of the gland does not always attend marked induration of the sore, nor is slight induration of the sore always accompanied by small swelling of the glands, though commonly this is the case. So also, though absence of tenderness is the rule, the glands may be slightly painful if pressed. Again, though the glands remain distinct in most cases, they have been known to coalesce into a single mass, which becomes fixed to the fascia. In many patients the dorsal lymphatic vessel of the penis becomes indurated sufficiently to be easily distinguished under the skin.

These buboes reach full development in one or two weeks, and remain without apparent change for several weeks, or even for two or three months. Then they begin to diminish slowly, but are generally still evident in the fifth or sixth month after infection, and now and then even for years afterwards. In rare cases the enlargement vanishes in two or three weeks. The long duration of enlargement renders these buboes a valuable sign of constitutional syphilis when the primary sore has disappeared. Again, the conspicuous enlargement of a group of glands may indicate the place of entry of the syphilitic poison when that is hidden.

TERMINATIONS.—In most cases the glands revert to their natural state. Sometimes they degenerate into masses of fibrous tissue. Now and then suppuration takes place, not from the syphilitic virus, but from pyogenic irritation. In tuberculous persons it is said that tubercular inflammation may supervene upon the syphilitic. The glands enlarge still more, coalesce, and slowly soften.

DIAGNOSIS.—This is generally easily drawn from the character of the swelling, aided by the presence of other syphilitic signs (hard sore, rash on the skin, &c.). These buboes may be confounded with chronic inflammatory enlargement, but in such cases the history and attendant symptoms remove doubt.

PROGNOSIS.—Apart from its connection with syphilis, the prognosis is good. The only untoward termination is tuberculosis.

TREATMENT.—Prophylactic treatment demands thorough disinfection of the sore in all cases. When possible it is desirable to apply pure carbolic acid or the caustic, cocaine or β -eucaine being used.

1. *Simple acute bubo*, from whatever cause it may arise, is treated like an acute abscess. In the early stages, purgatives, rest in bed, and constant application of a cream made of equal parts of extract of belladonna and glycerine, hot poultices, fomentations, or rags soaked in lead-lotion with an india-rubber hot-bottle over them are requisite. All operations should be done with full attention to asepsis, and infection from the primary sore must be carefully guarded against. The dressings should be dry when speedy union is expected, but when there is much suppuration and periadenitis, boric-acid or corrosive-sublimate (1:2000) fomentations are best. When a sinus is present without much glandular swelling, rest, with fixation of the hip in a Thomas's hip-splint, and constant elastic compression by cotton-wool and a spica bandage over a moist and antiseptic dressing, should be fairly tried. If heal-

ing does not occur, or if when first seen there are multiple sinuses or enlarged glands, the sinuses should be opened up, the cavity curetted, and the affected glands dissected out, or scraped out and carbolicised. These operations necessitate large wounds, and bleeding from the first branches of the femoral artery may be troublesome : the femoral vein has more than once been wounded.

If glands remain inconveniently swollen in spite of rest, constant pressure, and counter-irritation, they must be dissected out.

Should pus not form, subsidence of the glands may be aided by pressure with a pad and spica bandage. When pus has formed, or as soon as it becomes evident that the above treatment is not succeeding, and before much periadenitis has arisen, the gland or glands should be carefully dissected out without infecting the tissues. If this is done the wound will rapidly heal. If the gland is adherent to its surroundings, or lies in a periglandular abscess, a vertical incision, opening the cavity fully, should be made and the pus evacuated. The cavity should then be lightly curetted ; the walls dried and painted with phenol ; and the wound plugged with iodoform gauze. Early evacuation checks the undermining of the skin and prevents burrowing.

2. The *chancreoidal bubo*, not being distinguishable from an ordinary simple bubo during the inflammatory swelling and consequent suppuration, requires the same treatment as that given above. When its chancreoid nature has become clear, it should be treated as a chancreoid with iodoform and corrosive-sublimate fomentations, frequently changed, all discharge being wiped away from recesses at each change. If necessary 10 per cent. cocaine may be applied to the surface, followed by pure carbolic acid which is allowed to soak in. Should this fail to check the ulceration, the patient must be anaesthetised, the whole surface curetted and carefully cauterised, the surrounding area thoroughly disinfected, and the parts dressed as above directed.

Phagedena.—When the ulceration by its rapid extension and obstinacy deserves this title, if there be any suspicion of syphilis, the patient should be brought under the influence of mercury as quickly as possible, by giving two or even three grains of blue pill thrice daily, or by the injection into the thick muscles of the trunk of some suitable mercurial solution, such as that of Raggazzoni (perchloride of mercury, 1 part ; iodide of sodium, 1 part ; distilled water, 64 parts : 8 minims being a dose). When the patient's general health is good, the ulceration seldom fails to yield to iodoform and fomentations, applied thoroughly in the manner directed. While the nocturnal gnawing pain continues, morphine should be given. The cessation of pain is a signal that the eroding action has stopped. When iodoform alone is insufficient, the continuous warm hip-bath must be employed. By it pain is at once arrested and healing soon set in motion. As continual immersion in a bath becomes extremely irksome, the ulceration may in many cases be arrested by keeping the patient in water for sixteen hours every day, and allowing the night to be passed in bed—in this interval the wound should be carefully packed with iodoform and fomented. When the ulceration is stopped, the bath may be discontinued, and iodoform alone used. If the water-bath fail, curetting and phenol or the caustic must be used.

The strength of the patient, generally much exhausted, should be restored by tonics, good diet, stimulants, and other general means.

3. The *syphilitic bubo* usually causes no trouble, and gets well during the course of treatment which is carried out for the cure of the general disease. If tenderness or aching occur, rest and a few warm baths are sufficient. If suppuration takes place the gland must be either enucleated, or incised and fomented. Should syphilitic glands become tuberculous and give rise to chronic abscesses, they should be dissected out and every attention should be paid to general hygiene. The treatment of syphilis must be continued.

BERKELEY HILL.

H. LITTLEWOOD.

BUHL'S DISEASE.—A synonym for Icterus Neonatorum.

BULB.—A synonym for the globe of the eye, and also for the medulla oblongata. Its adjective, 'bulbar,' is commonly restricted in application to the latter, and has for a considerable time been commonly thus employed, as in the terms 'bulbar symptoms,' 'bulbar nerves,' and the like. This use of the adjective has led to a more extensive employment of 'bulb' for the medulla oblongata, because the term 'medulla' is also applied to the spinal cord, the 'medulla spinalis,' as well as in its general sense of 'marrow.'

BULBAR PARALYSIS.—A synonym for labio-glosso-laryngeal paralysis; derived from the pathological relation of the disease with the bulb or medulla oblongata. See LABIO-GLOSSO-LARYNGEAL PARALYSIS.

BULIMIA (βοῦς, an ox; and λιμός, hunger).—Excessive or voracious appetite. See APPETITE, Disorders of.

BULLA (bulla, a bubble).—See BLISTER.

BURNS.—The morbid local effects produced by the direct application of excessive dry heat. See HEAT, Effects of Severe or Extreme.

BURSÆ MUCOSÆ, Diseases of.—Bursæ mucosæ are spaces in the connective tissue lubricated with a small amount of serous fluid, and situated at points exposed to repeated pressure or friction. Structurally they are composed of a layer of condensed connective tissue, fusing externally with the areolar tissue of the part, and lined internally with an imperfect layer of flattened endothelial cells, similar to those found in the pleura or peritoneum. Bursæ are normally present in many parts of the body; but new bursæ, equally perfect in their structure, may form at any part exposed to abnormal pressure and friction, as over the outer malleolus of a tailor, under an old corn, or over the head of the metacarpal bone of the great toe (*bunion*). Like the great serous cavities, bursæ are in direct communication with the lymphatics, and inflammatory products are consequently absorbed from them with great readiness, often giving rise to a diffuse inflammation of the surrounding areolar tissue, closely resembling phlegmonous erysipelas in appearance, and always accompanied by high fever.

Bursæ are liable to the following diseases:—

1. **Acute inflammation and suppuration**—**Acute bursitis.**—This is usually the result of

some more or less violent mechanical injury, some abrasion of the cuticle over the site of the bursa providing a means for the infection of its cavity with pyogenic organisms. This disease may occur in any bursa, but is most common in the bursa patellæ, in that over the olecranon, and in the small false bursa formed beneath an old corn, or in a bunion. The symptoms are those of acute inflammation generally, but the redness and swelling often extend a considerable distance up and down the limb. Thus, a drop of pus beneath a corn may cause œdema and redness to the knee. The febrile disturbance is usually proportionately severe.

TREATMENT.—Hot fomentations, and the application of glycerine and extract of belladonna (equal parts), may be of use. An early incision into the inflamed bursa is very desirable, and pus, if present, should be let out at once, for it may burrow extensively, especially about the knee. The treatment of the wound should be carried out on strictly antiseptic lines. The incision not uncommonly reveals the fact that there has been hæmorrhage into the cavity of the bursa.

2. **Chronic Bursitis—Dropsy of the bursa.**—This consists of an accumulation of serous fluid distending a bursa more or less tensely. The wall becomes somewhat thickened and opaque, but is otherwise unchanged. The contents are either fluid or jelly-like in consistency, clear, straw-coloured, and albuminous in character. The cause of the disease is usually repeated slight mechanical injury. The symptoms are merely those of a collection of fluid in the situation of the bursa, perhaps accompanied by a feeling of weakness in the neighbouring joint. There is no pain or tenderness. The commonest form of this disease is the so-called 'housemaid's knee,' but it is not infrequent in the bursa which lies in the popliteal space between the semi-membranosus muscle and the inner head of the gastrocnemius.

TREATMENT.—Avoidance of the mechanical injury, whatever it may be, which has caused the disease, is most important. A series of small blisters may be applied over the swelling; or, provided the bursa does not communicate with the neighbouring joint, it may be tapped and pressure then applied to it for a few days. If these fail, an incision may be made into the swelling with antiseptic precautions, and the bursa dissected out, or the closure of the cavity may be insured by the application of liquefied carbolic acid, or of a strong solution of zinc chloride, so as to destroy the lining. In the case of the popliteal bursa, which normally communicates with the knee-joint, if active measures are necessary, aspiration followed by pressure may be tried, or the bursa may be dissected out.

3. **Chronic enlargement of the bursa, with fibroid thickening of its walls.**—This affection is most common in the bursa patellæ, but may occur in that situated over the olecranon or in that over the tuberosity of the ischium. The bursa becomes converted into a dense fibroid mass of almost cartilaginous hardness. On section it is found to be composed of concentric layers of dense fibrous tissue. There is usually a small central cavity containing a little fluid. The cause of this change, as of simple dropsy, is repeated mechanical injury of a slight nature. In some cases it seems to be connected with syphilis. The only treatment is removal by the knife.

4. **Chronic enlargement of the bursa, with the presence in it of the so-called melon-seed bodies.**—In this form of disease, in addition to some thickening of the wall and accumulation of fluid in the bursa, small oval, flattish, smooth bodies of a white colour are found floating freely in its interior. These are similar in nature to those found in some forms of ganglion (*see* **GANGLION**). This condition is recognised by the peculiar soft crackling feeling perceived on palpation, combined with the ordinary symptoms of an enlarged bursa.

TREATMENT.—The affected bursa may be dissected out; or the alternative treatment given under 'chronic bursitis' may be applied.

5. **Tubercular disease.**—The bursa most often affected is that over the great trochanter of the femur beneath the gluteus maximus muscle. The cavity may be filled with tuberculous granulation-tissue, or a layer of this tissue may line the cavity, and the latter may then become distended with semi-fluid products resulting from progressive necrosis of the surface of the lining membrane and from serous exudation.

TREATMENT.—If not too large, the bursa may be dissected out. Or it may be laid freely open and its cavity thoroughly scraped out so as to

remove the whole of the lining membrane. The fibrous sac remaining should be treated with liquefied carbolic acid or with strong zinc-chloride lotion and the wound subsequently sutured with or without drainage, according to circumstances.

6. **Syphilitic disease.**—Effusions into bursæ in secondary syphilis are rare. Gummata of bursæ (most frequently of the bursa patellæ) are much more common. The gumma usually supervenes upon the condition described under section 3, and both knees are often affected. The cavity of the bursa becomes filled with the inflammatory products, and these subsequently undergo necrosis. The skin over the summit of the bursa becomes adherent and may give way later. Thus is produced a characteristic punched-out cavity with undermined edges and with a yellow adherent slough on its floor.

TREATMENT.—The bursa should be excised, and appropriate constitutional treatment adopted.

BUXTON, in Derbyshire.—Simple thermal waters. *See* MINERAL WATERS.

BUZIAS, in Hungary.—Strong muriated chalybeate springs. *See* MINERAL WATERS.

C

CACHEXIA (*κακός*, bad; and *ἔξις*, condition).

The term Cachexia is applied to the state of general constitutional disturbance produced by some grave disease. It is most frequently used of the condition presented by patients suffering from malignant tumours, but it is also sometimes applied to the state of ill-health caused by syphilis, dysentery, malaria, and other chronic maladies. The subjects of cachexia are generally wasted, anæmic, and debilitated; the skin is wrinkled and inelastic, and often presents a yellowish tinge. The tongue is generally furred, the breath foul, and the appetite absent or disordered.

To explain the cachexia associated with malignant growths it has been suggested that the cells of tumours may give rise to some harmful product which acts as a general poison. There is little evidence in favour of this view. Tumours may grow to a large size without giving rise to cachexia, the occurrence of which is generally explicable on the ground of interference with the digestive processes or as a consequence of the drain on the system caused by the continued discharge from an ulcerated surface.

W. CECIL BOSANQUET.

CADAVERIC (*cadaver*, a dead body).—This word signifies 'belonging to the dead body;' and it is applied to the aspect, colour, odour, and other phenomena resembling those of death, which are sometimes observed in the living subject.

CADAVERIC RIGIDITY.—*See* **DEATH**, Signs of.

CAISSON-DISEASE.—**SYNON.** : Compressed-air illness.—Caisson-Disease is the name given to the illness which is produced by immersion in an atmosphere of compressed air. Immersion in such an atmosphere is involved by the now extending practice among engineers of carrying out subaqueous undertakings, such as the sinking of the foundations of bridges and the boring of tunnels through a water-bearing soil, by the assistance of an artificially compressed atmosphere. With this assistance larger volumes of water can be kept out of the working space than could possibly be dealt with by mere pumping. The illness to which the workers are liable resembles in many respects that which is met with among divers.

The workmen enter the atmosphere of compressed air by means of an 'air-lock' provided at each end with a door opening towards the compressed air; in this lock or chamber the pressure is raised gradually; about 2 or 3 minutes are usually allowed for raising the pressure to 30 lbs. per square inch above the normal.

SYMPTOMS.—The raising of the pressure may be accompanied by pain in the ear, due to closure of the Eustachian tube which prevents the increased pressure reaching the middle ear. If this warning pain be disregarded, rupture of the tympanic membrane may take place, and suppuration of the middle ear may follow. These disorders are often absent, depending only on the accidental lack of patency of the Eustachian tube.

The characteristic symptoms of the illness follow the *exit* from the 'air-lock', which, like the entrance, has to be accomplished slowly. These symptoms may commence immediately the pressure is lowered or may be postponed until some hours after coming

out: the usual interval is from a few minutes to one hour. By far the most common symptom is pain in the extremities, known by the workmen as 'bends.' The pain mostly affects the legs, and principally the parts about the knees. It may be present in one or all of the limbs. It has a sudden onset and rapidly increases for a short time afterwards. The pain may be only slight or it may be of a very severe character. Usually there is no local physical sign. It may pass off in a few hours, or may last for one or two weeks. In a small number of cases severe epigastric pain occurs as well.

In severer cases paraplegia results with or without loss of control over the bladder and rectum. Occasionally the less common symptom of auditory vertigo is met with, generally accompanied by partial deafness and sometimes tinnitus. Attacks of unconsciousness have been described; formication sometimes occurs; epistaxis and hæmoptysis are rarer events. Entry into a compressed-air chamber is in most cases accompanied by a slowing of the pulse and a rise of blood-pressure.

ÆTIOLOGY.—The name of the illness is derived from the fact that while the boring operations are proceeding downwards the compressed atmosphere is contained in the vertical cylinder or *caisson* which is being sunk; when, as in tunnelling operations, the boring is horizontal, the caisson may or may not contain compressed air; the latter may be contained in the tunnel itself; the name therefore indicates neither the causation nor the nature of the illness.

Among the factors which influence the incidence of the disease are the following:—

1. The degree of pressure. The higher the pressure the more numerous and severe are the cases of illness.

2. The duration of the exposure. The longer the stay in the compressed atmosphere the greater is the liability to illness.

3. The purity of the compressed air. The better ventilated the compressed atmosphere the less frequent are the illnesses. The importance of this factor was clearly demonstrated during the construction of the Blackwall Tunnel, where the pressure went up to a maximum of 37 lbs. to the square inch above the atmospheric pressure: it was there shown that the number of cases of illness varied inversely with the amount of fresh air pumped in. At high pressures, however, a very large supply of air, even as much as 12,000 cubic feet per head per hour, may be necessary to minimise the danger.

4. By most observers it is stated that the arrangements for exit form a considerable factor in the causation of the illness; and it is probable that the liability to illness is increased whenever this process is accomplished too rapidly.

5. Certain personal conditions appear to have some influence: (a) Plethoric persons are especially liable to be affected; (b) older men are more apt to suffer than younger men, and (c) those newly employed than the older hands; (d) excessive drinking and great fatigue are predisposing causes.

PATHOLOGY.—Very numerous theories have been advanced to account for the illness; that most worthy of attention was formulated by Paul Bert, who suggested that the symptoms depended on the increased solution of gases by the blood during the sojourn in compressed air, and on their escape during 'decompression.'

PROGNOSIS.—The most common symptom, pain in the limbs, is of the least serious import; the pain often disappears by itself in from one or two hours to one or two weeks. The epigastric pain may assume an alarming character, but usually does not last long. Paralysis usually passes off in a few weeks unless accompanied by bladder-troubles; the fatal cases have generally died from cystitis and bedsores. In the cases of auditory vertigo associated with affection of the internal ear the prognosis may be said to be generally good, though partial or complete deafness may be permanent; in exceptional cases the attacks of vertigo may continue for years.

TREATMENT.—1. *Preventive.*—The indications for prevention have been sufficiently considered in the section on ætiology.

2. *Curative.*—If the patient is seen soon after the commencement of the illness, 'recompression' generally allays the symptoms in a marvellous way, and this improvement may be maintained if the recompression be followed by a very slow exit of, say, half or three-quarters of an hour. A medical air-lock is therefore an important adjunct to any large engineering works where compressed air is used. Rubefacient liniments are useful for persisting 'bends'; anodynes may be of service in some cases. Paraplegia, occurring as a complication, must be treated on general medical principles. Prolonged cases of vertigo are but little amenable to treatment.

E. HUGH SNELL.

CALCAREOUS DEGENERATION.—A form of degeneration characterised by the deposit in the tissues of earthy salts, especially those of calcium. See CONCRETIONS.

CALCULI (*calx*, chalk).—The term 'calculus' is now applied to any kind of concretion formed in the ducts or passages of glandular organs. See CONCRETIONS.

CALIPERS.—An instrument employed for measuring diameters, used more especially in clinical medicine for measuring the head and chest. See PHYSICAL EXAMINATION.

CALLOSITY (*callositas*, *callum*, hard skin).—A local thickening of the horny layer of the epidermis due to intermittent pressure, slight friction, or chemical irritation, continued over a considerable period. See CORN.

CALLUS.—The reparative material formed by proliferation of the periosteum and other tissues around the ends of a broken bone. The exact structure of callus varies with the time which has elapsed since the fracture. At first it consists of tissue closely resembling granulation-tissue (*provisional callus*); later on it contains cartilage, osteoid tissue, and fibrous tissue. The tissue actually uniting the broken ends finally undergoes true ossification (*permanent or definitive callus*).

CALVITIES (*calvus*, bald).—SYNON.: *Alopecia calva*.—A synonym for baldness. See BALDNESS.

CANARIES, The, in North-east Atlantic Ocean; Teneriffe.—Mean temperature in winter, 64° to 85°. Warmer, drier, but more variable, than Madeira. East winds from Africa. See CLIMATE, Treatment of Disease by.

CANCER (*cancer*, a crab).—SYNON.: *Carcinoma*; Fr. *Cancer*; Ger. *Krebs*.

DEFINITION.—The word 'cancer' is without histological meaning. We find it and its synonym *carcinoma* used as long ago as the time of Hippocrates, and the latter term was then applied to any new-growth of a malignant character. The name originated in the large ramifying veins and puckered furrows which spread from a cicatrising cancer that is involving the skin. When the broad distinction between the epithelial and connective-tissue types of tumours was established by Virchow and others, it was decided to retain the word *cancer* as the name for the more malignant or epithelial growths; while the equally meaningless but less formidable word *sarcoma* has been, from this time, confined to those tumours which have connective tissue for their type. See TUMOURS.

In this sense of the word the cancers form a class which is, on the whole, easily distinguished by definite microscopical and clinical characters; but at two points, at least, the difference from simpler growths is almost imperceptible. First, as a matter of accident, one sarcoma (the alveolar) resembles a cancer so closely in microscopical structure that it is impossible to distinguish between them without reference to clinical facts; and, in the second place, as cancers are essentially depraved modifications of epithelial, epidemic, or glandular structures, they may be found to differ so slightly in histological characters from simple hypertrophies that the fact of ultimate malignancy is often all that can decide between, say, a papilloma and an epithelioma, a glandular cancer of the rectum and a simple polypus, or a scirrhous of the breast and an adenoma.

ÆTIOLOGY.—Before speaking of the minute structure of cancer it will be well to consider what is known of the nature of this morbid process. In what follows, sarcoma is regarded equally with carcinoma, since their general laws are approximately the same.

The term 'malignant' applied to both these classes of tumours was originally used merely in the sense of destructive, incurable, and fatal; recently it has received a more exact meaning, founded on the mode of growth and characters of these neoplasms as distinguished from simple tumours. Malignant tumours show the following characters: (*a*) local extension from the point of origin, causing infiltration or destruction first of the part originally invaded, and later of surrounding parts; (*b*) wider extension, by mechanical means, chiefly through the lymphatic or blood-circulation, so as to produce secondary foci of disease—similar to the primary focus; (*c*) a general affection or intoxication of the whole body, leading to malnutrition or cachexia; (*d*) the malignant growth is persistent, and does not subside of itself, spontaneous arrest of growth, if it ever occurs, being exceedingly rare.

These characters sufficiently distinguish malignant growths from simple tumours, and suggest that though these two classes of growths may be sometimes much alike in minute structure, they may be due to entirely different causes.

On the other hand the 'malignant' characters do not distinguish cancer in the wide sense from specific infections and inflammations, especially from the more chronic kinds. Local extension or infiltration is shown by the inflammations due to pyogenic cocci; still more by syphilitic, tubercular, and leprosy lesions. The difference in 'malignancy'

between lupus, destructive syphilitic lesion, and rodent ulcer or epithelioma is mainly one of degree. The specific infections may be distributed through the body in the same way as malignant growths, and produce marked intoxications or cachexia.

On these grounds carcinoma at all events (even if the conclusion is less clear as regards sarcoma) must be regarded not as a growth only but as a specific morbid process comparable to the specific diseases produced by microbes. However, there are certain differences between malignant diseases and the specific microbial diseases which cannot be ignored.

1. In cancer the elements first affected are not destroyed, as in cases of infection, but are stimulated to enormous overgrowth.

2. In malignant disease there is little local defensive reaction (inflammation) or perhaps none at all, apart from contamination with pathogenic organisms.

3. In malignant disease, though a rise of temperature is sometimes observed, fever is not commonly produced.

4. The secondary growths of malignant disease are produced, so far as is known, by transplantation of cells of the original growth to other parts of the body. But the secondary foci of specific inflammations may be set up by the conveyance of the microbes which caused the original focus of disease, the cells of the tissue first affected not taking any part in the process.

These differences appear to some pathologists fundamental; but nevertheless the opinion is gaining ground that malignant disease may, like the specific infections, be due to some specific living organism—in other words, that *cancer may be a parasitic disease*.

Very numerous researches, of which we can only give the barest outline, have been devoted to discovering some pathogenic parasitic organism in cancer. In the first place, as was natural, search was made for bacteria, but the result of these researches has been entirely negative.

Another class of organisms suspected of causing cancer is the protozoa. Certain appearances in the cells of cancer were thought to indicate the presence within them of animals of the order Sporozoa allied to the coccidia found parasitic in the liver. But these supposed organisms have never been isolated or cultivated, so that they are not proved to be living organisms, and they are now generally regarded as due to degenerative changes merely. A third class of organisms which has been supposed to be the parasitic cause of cancer-growth is that of yeast-fungi (Blastomycetes). Various appearances in cancers have been thought to indicate the presence of such organisms, the appearances being partly the same as those formerly interpreted as sporozoa. These bodies have been observed especially by Italian pathologists, Sanfelice and Roncali; and also by Plimmer and others in this country. Further it has been shown (first by Sanfelice) that yeast-organisms obtained from fruits, if injected into animals, are capable of producing tumour-like masses which have been regarded as true new-growth. Finally, yeast-organisms have been cultivated from cancer-tissues (by Plimmer in a long series of cases), which introduced into animals have produced tumour-like masses resembling those produced by yeasts from vegetable sources.

Against this it is objected that the masses produced in experiments on animals by blastomycetes are only inflammatory or granulation-tumours, not true tumours: further that the mere presence of blastomycetes in cancerous growths, even if proved, does not show that they have any causal relation to them.

From the facts of which a broad outline has been given above, we should conclude that the parasitic theory of cancer is not yet established; it has not been proved that cancer is caused by bacteria or sporozoa or blastomycetes, or any other organisms.

In support of the theory of a specific origin for cancer some other considerations have been adduced.

1. Contagion.—Though cancer is certainly not in the ordinary sense contagious, there are facts showing that it may be transplanted from one part to another of the same individual. Also in very rare cases, it has been thought to pass from one person to another having very intimate relations, such as those of husband and wife, by local contagion. Cancerous tumours of certain animals have also been transplanted to other animals of the same species; but the process resembles grafting more than inoculation.

2. Local Distribution.—Careful observation has shown that cancer is more prevalent in some countries or districts than in others. Moreover certain dwellings appear to confer on their successive inhabitants a special liability to cancer: so that the existence of 'cancer houses,' in rural districts, where there is little movement of population, seems to be well established. The favouring physical conditions, if any, are imperfectly known, but certain river-valleys and low-lying basins have been thought to show special liability. These considerations would seem to point to some specific external or exogenous cause.

Assuming from the above facts that there is ground for regarding cancer, at least provisionally, as a specific disease, we will point out the best known favouring conditions and laws of the disease.

1. Age.—No disease is more distinctly a disease of later life than cancer. It is very rare under twenty-five; and probably most of the deaths recorded in early life as due to cancer are really cases of sarcoma. The deaths below thirty-five are comparatively few, and the largest number of deaths occurs between fifty-five and sixty-five. But if regard be had to the actual number of persons living at successive age periods, the liability to cancer is seen to go on increasing up to advanced age.

Sex.—It is generally recognised that cancer is commoner in the female sex than in the male; the difference being chiefly due to the predominance of cancer of the generative organs in the former.

General Health.—There is no reason for thinking that any kind of cachexia or ill-health predisposes to cancer. On the other hand, the subjects of this disease are generally free from other disease, and on the whole robust. It is thought to be more prevalent in long-lived families, and probably with justice.

Habits of Life.—Poverty, want of cleanliness, and what is generally called bad hygiene, do not at all favour the production of cancer. It is supposed, though not easily proved, that it is commoner in the upper classes than in the lower. Abundant nutrition and it would seem especially abundance

of animal food are favouring causes. It has been supposed that dwellers in the country are more liable than town-people, but at the present time the 'cancer death-rate' both for England and Scotland is distinctly higher in towns than in rural districts.

Heredity.—It seems clear on the whole that the children and descendants of those who have died of cancer show more than the average liability to the disease. This inherited liability is distinctly more marked in women than in men; and in the former is especially seen in cancer of the reproductive organs. It is not supposed that a germ or seed of cancer is inherited, but only a greater predisposition to become affected by the disease. Since cancer rarely causes death before the reproductive age, this inherited predisposition seems *a priori* likely to become more widely spread in the population.

Nervous influence.—It has been thought that depressing causes acting on the nervous system, such as shock, grief, &c., predispose to cancer, but the number of cases of this kind is too small to establish an induction.

Chronic Inflammation or Trauma.—It has often been observed that cancer occurs in tissues which have been exposed to chronic traumatic irritation leading to inflammation. The effect of smoking, especially pipes of a certain kind, in predisposing to epithelioma of the lip or tongue; and of alcoholism, in predisposing to cancer of the stomach; the occasional growth of epithelioma on the basis of lupus, and of carcinoma on chronic gastric ulcer, and other instances might be quoted. The liability of chimney-sweeps to cancer is a fact of the same kind. Occasionally an acute trauma has been apparently the starting-point of cancer. These facts seem to show that damaged tissues are more liable to the invasion of cancer, but do not explain that invasion.

Increase of Cancer.—The increase is generally more rapid in males than in females, especially in England; but this difference is much less marked in Scotland. Since the predominant cancers of the male sex are those affecting the digestive organs, while in the female sex cancers of the breast and the uterus predominate, the difference points to the conclusion that the increase of cancer is largely due to increased frequency of cancer of the digestive organs. Where statistics of cancer show the part of the body affected (as in Ireland), it is found that cancer of the digestive organs, including cancer of the tongue, increases more rapidly than the average increase; but that there is an increase in cancer of the reproductive organs in women, including the mamma. In St. Thomas's Hospital 'digestive cancers' have come to predominate over those of reproductive organs, even in the female wards.

It has been objected that cancer is now more certainly diagnosed and more accurately registered than in former days, and that therefore the increase shown by statistics is only apparent. But though this objection might have weight if the comparison were with the statistics of thirty or forty years ago, it would not explain the increase during the last ten years in which the conditions of diagnosis and registration have remained virtually constant. The objection is supported by the consideration that the increase being chiefly in the male sex refers to internal cancers which are more difficult of diagnosis. But the more rapid increase of cancer in males is not so marked in other countries as in England. Moreover, this would not account for the

increasing cancer in the breast and the tongue, about which, especially when fatal, there is no difficulty in diagnosis. Moreover, the increasing success of operation in curing cancer of accessible parts is a factor which ought to tell in the contrary direction. So that there seems no reasonable ground for disbelieving in an actual increase of cancer: and this is now admitted by the heads of the statistical departments in England, Scotland, and Ireland.

The explanation of this increase of cancer is very difficult. It has been supposed to be due to an increased average longevity of the population, by which a larger proportion of the population survive to the age at which they are liable to cancer. But the census of 1891 *did not* show a larger proportion of persons in the United Kingdom living at the higher ages, as compared with 1881. On the contrary the proportion living at certain age periods above thirty-five was even less than it had been. Moreover, Dr. Newsholme has shown that if the cancer-mortality is calculated only for the population at higher ages (above thirty-five), there is still an increase in the registered mortality from cancer. Another explanation is that the improved diet of the working classes who form the mass of the population, and especially the enormous increase in the consumption of meat, have brought them into the state of nutrition most favourable to cancer. Considering the predominance of cancer of the digestive organs, this explanation has much plausibility. But observations in countries where the customs of diet are different are needed to confirm it. The partial explanation suggested by the facts of heredity has been already referred to.

On the whole, we must conclude that the cause of the increase of cancer, like the cause of cancer itself, is yet undiscovered.

HISTOLOGICAL STRUCTURE.—Histologically, cancers are distinguished by consisting partly of cells of an obviously epithelial origin and partly of connective tissue. The connective tissue forms alveolar spaces, and may vary in structure from a loose fibro-cellular material to strong and old fibrous tissue. The alveolar spaces communicate with each other and contain the epithelial cells. These vary much in shape, size, and arrangement, but are always easily separable from the surrounding connective tissue, while they are never separated from one another by a stroma of any sort.

CLINICAL CHARACTERS.—Clinically, cancers are distinguished by the structures in which they originate; by the method of their recurrence and their mode of growth; as well as by a few characteristics apparent to the eye and touch.

Seat.—As their nature would *a priori* have rendered almost certain, cancers probably never originate except in connection with epithelial or epidermic structures—i.e. in skin, mucous membrane, or secreting glands; but as the epidermis and epithelium, the original upper and lower layers of the embryo, are widely diffused throughout the body, and often intimately associated with the descendants of the cells of the middle layer, it is not surprising that primary cancers have been described as occurring in organs which have their origin from connective tissue only. Such are the instances of primary cancer of bone and lymphatic glands, the possibility of the occurrence of which may be at present considered undecided.

Recurrence.—The first recurrence is almost with-

out exception in the lymphatic glands, which collect their supply of lymph from the seat of the original tumour; when this has occurred the process may be repeated in the next proximal lymphatic glands, or numerous distinct tumours may appear in different parts of the body; but if a single growth occur in another locality without previous glandular enlargement, the case may probably be looked upon as one of double primary development. A soft cancer may break into the abdominal cavity, where its small particles may stick to various parts of the peritoneum and form the starting-points of new growths (disseminated cancer of the peritoneum); it is probable that a similar seeding may take place into the lungs when an ulcerated epithelioma projects into the trachea. The recurrence is usually of precisely the same structure as the original growth.

Mode of growth.—Cancers increase in size by infiltration of the surrounding tissues, and this gives rise to the very important clinical facts that they are not enclosed by a capsule like many simpler growths, and that they have a great tendency to implicate the skin and cause ulceration.

Naked-eye appearances.—The contraction of the connective tissue forming the alveoli in its advance towards fibrous tissue gives rise to puckering of the surrounding skin; and the looseness of the connection between the epithelial and connective-tissue elements causes a milky juice, consisting of the former, to escape on scraping a recent section. This characteristic was made much of by our predecessors before the word *cancer* had lost its inclusive meaning; we know now that many rapidly growing *sarcomata* yield a similar juice, but in less abundance than cancers; and thus it has come to pass that a milky juice is now more diagnostic of the malignancy than of the genetic origin of the growth.

This completes the list of the signs by which cancers may be distinguished from other tumours. Tables have been published to show the relative frequency with which cancer attacks different organs; they are not, upon the whole, trustworthy, and this question will be best considered in discussing the subdivisions of the genus.

CLASSIFICATION.—The subdivisions of cancers are as follows:—

<i>Hard cancer</i> or <i>Scirrhus</i> .	}	GLANDULAR TYPE.
<i>Soft cancer</i> or <i>Encephaloid</i> .		
<i>Lobular</i> or <i>Flat-celled Epithelioma</i> .	}	EPITHELIAL and EPIDERMIC TYPE.
<i>Cylindrical Epithelioma</i> .		
<i>Colloid cancer</i> .		

Typical hard and soft cancers stand obviously at opposite ends of one series which is built upon the type of the secreting gland: between the two are an infinitude of intermediate stages. The two forms of epithelioma are, quite as evidently, monstrous growths of skin or mucous membrane. Colloid is probably the result of degeneration of any one of the other forms. Besides these, other varieties are often mentioned which do not justify a more complicated classification; among these are tumours, which though of nearly normal glandular structure are nevertheless malignant, and those which have received the names *melanotic*, *telangiectatic*, *osteocancer* &c.

DIAGNOSIS.—The diagnosis depends upon the clinical characters of the several groups. That of

an advanced case of cancer is generally easy; in the early stages it is mostly impossible.

PROGNOSIS.—The prognosis is always bad, especially in encephaloid cancer, but least so in epithelioma; this suggests the much-debated question of the constitutional nature of the disease. If in its origin a cancer be purely local, early removal ought to effect a permanent cure; but if there be at the bottom a constitutional taint, a reprieve should merely be granted until a suitable fresh irritation arise.

COURSE.—The course of a cancer depends upon its seat, and the symptoms must accordingly be sought among the articles on diseases of special regions. If, however, life be not shortened as a result of interference with the functions of the organ attacked, death is caused either by marasmus—the result of prolonged suppuration and pain—or by extensive or repeated hæmorrhages. The rate of progress is more slow as age advances.

TREATMENT.—The treatment of cancer in the early stages belongs to the surgeon, the practitioner giving such counsel as will improve the general health and support the strength. In the later stages the physician may be called upon to treat symptoms; but up to the present time all the specifics introduced either by regular practitioners or by charlatans have proved quite inefficient, if not actually harmful.

We shall now discuss the varieties of cancer.

I. Scirrhus.—Scirrhus, as its name implies, is among the hardest of tumours, if bony growths be excepted. Its hardness, as compared with soft cancer, depends upon the large proportion which the alveolar stroma bears to the contained cells; and this is probably the consequence of the soil in which the tumours originate, and the rapidity of their growth, rather than of any specific difference between them.

Seat.—The female breast is the most common seat for scirrhus, but it also occurs in the stomach, uterus, tongue, œsophagus, and the liver and other glands, and it has been described as primary in the prostate, testicle, skin, and other structures.

Naked-eye appearances.—A section through the centre of a matured hard cancer of the breast presents to the naked eye well-marked and constant appearances, which, with the exception of such peculiarities as are due to the situation, will serve as a description of such a tumour occurring elsewhere. These are clearly explained by the microscopical arrangement, and, when looked at by the light which it affords, fully account for all the clinical characters. The knife passes through it with a creaking noise, and the cut surfaces are at once hollowed in the centre. There is not a sharp edge to the growth, and the circumference is of a greyish or pinkish-white tint, projecting a little above the surrounding tissues, into which it sends small lobular prolongations; the hollow centre is very hard and of a glistening white colour. Scirrhus is evidently fibrous in structure, and receives from all quarters fibrous bands, which often extend far into the fat of the breast or the skin, and some of which can nearly always be traced to the principal milk-ducts. Between the centre and the edge the greater part of the tumour is on the whole of a pinkish-yellow colour, but notably pink and soft externally, and yellow and hard internally. The surface yields a milky juice on scraping, and may in certain cases show some of

the following appearances, which are, however, accidental: round the circumference little masses of healthy fat may be included, though this but rarely happens; cysts containing grumous grey or red fluid may have formed by the breaking down of the new-growth or by hæmorrhage; or such a hæmorrhage may have resulted in patches of yellow or even black pigmentation.

Microscopical appearances.—Without discussing the merits of the opposing theories as to the origin of cancer-cells, the following may be taken as the undoubted microscopical appearances of scirrhus. The grey outer layer is made up of indefinite smallish round cells, resembling white blood-corpuscles, infiltrated through the tissue into which the growth is spreading, among which are scattered a few which have the appearance of epithelial cells. The next or pink layer represents full development, and shows fibro-cellular stroma, enclosing large epithelial cells, and containing a copious supply of vessels. In the third or yellow layer the stroma has become fibrous, and the cells are undergoing fatty degeneration; and in the inner white centre the cells are replaced by indefinite masses of granular debris, and the stroma consists of firm and old fibrous tissue. See Plate, figs. 8, 10, 11.

Clinical features.—The relation of these appearances to the clinical peculiarities of scirrhus is as follows: the excessive hardness is explained by the great development of fibrous tissue; the peculiar indefiniteness of the edge, and the tendency to involve the skin and ulcerate, by the manner of growth; while the puckering, retraction of the nipple, and indirectly (from the manner in which cutaneous nerves are involved) the pricking and shooting pains, are due to the contraction or cicatrization of the stroma. To the latter is also due a very important but not generally recognised diagnostic character of an early scirrhus—namely that long before the skin is involved it is seen to be dimpled when gently moved to and fro over the growth.

A scirrhus which has involved the skin forms a purplish-red, flattened, and shining tumour, covered with small veins and tender to the touch. The ulcer which results from its breaking down is ragged, with a hard base and hard irregular undermined edges, and a dirty surface covered by knobby masses resembling granulations, which have a great tendency to bleed, and often slough. After removal it often returns in the scar. When occurring in the liver it is softer than elsewhere, and the name of scirrhus-encephaloid is often given to it. See fig. 7.

II. Encephaloid.—Encephaloid, medullary, or soft cancer, so named from its usually brain-like appearance and consistence, is softer and grows more rapidly, and is more frequently observed in internal organs than scirrhus, often indeed forming enormous intra-abdominal tumours.

Seat.—It has hitherto been observed as primary in the salivary and mammary glands, testicle, ovary, and prostate, the thyroid body, and in the mucous membrane of the nose, the liver, and the stomach. It has with some degree of looseness been called the cancer of childhood by those who consider scirrhus as almost peculiar to mature age.

Naked-eye appearances.—To the naked eye a fresh section usually presents a convex surface; it is whitish, but generally mottled by coloured patches the result of old or recent hæmorrhages; and yields very copiously a milky juice on scraping.

Microscopical appearances.—Encephaloid cancer

differs from scirrhus only in the relative proportion of the two chief factors. The cells are more numerous and are contained in larger spaces; they are sometimes small, but generally much larger than in scirrhus; and the stroma is delicate and fibro-cellular and very small in amount. See fig. 9.

Its method of extension is the same as that of other members of the class. It is by far the most malignant form of cancer, because of its rate of growth and recurrence, and the rapidity with which it causes general cachexia.

III. Lobular Epithelioma.—Lobular or squamous epithelioma, epithelial cancer, or cancrroid, develops in connection with skin and mucous membrane, and, though consisting essentially of squamous epithelium, may start from a part which is covered by the cylindrical variety. It occurs near the natural orifices of the mucous tracts—as, for example, on the mouth and tongue, anus, penis, or vulva; but also at other parts of the skin—as on the scrotum (chimney-sweep's cancer) and at the upper end of the œsophagus. The history of a local irritation as its origin is often obtainable, but more frequently nothing of the kind can be discovered.

Naked-eye appearances.—The first appearance is that of a pimple, which soon breaks down in the centre, forming a small sore. When fully developed there is an irregular ulcer, with an extensive, hard and nodular, generally inflamed base and circumference; the edges are abrupt or undermined, and the floor grey or reddish, very uneven, discharging a foul pus, and with a great tendency to bleed. As a rule there is considerable pain, and the proximal lymphatic glands are very generally enlarged. A section to the naked eye shows a number of minute cylinders of yellowish-white colour, cut sometimes longitudinally, sometimes transversely, fusing together into an indefinite mass superficially, but more or less discrete below, and infiltrating the subjacent tissues. On squeezing the section little nodules like sebum appear on the surface.

Microscopical appearances.—The cylinders or lobes of epithelioma are found to be made up of squamous epithelium, the cells of which generally exhibit in parts a crenated margin (Max Schultze's 'prickle-cells'). As in the skin, the deeper—that is the circumferential—layer of cells in each lobe, which are the youngest, are roundish or oblong, with large nuclei which stain readily; further in, the cells are larger and flatter, and in the centre are found the well-known globes or nests. These were at one time considered peculiar to epithelioma, but are now known to occur in warts and corns; they consist of onion-like arrangements of epithelial cells, varying much in size and the number of concentric layers, and containing in the centre sometimes an amorphous mass, sometimes large and irregular cells. The tissues beneath and between the lobules are infiltrated with small cells, and often contain in sections what appear to be isolated masses of epithelium; these are, however, the ends of divided divergent lobules. Opinions differ as to the exact starting-point of an epithelioma, the share which the sweat and other glands take in it, and also as to the rationale of the formation of the globes. See fig. 2.

Epithelioma seems to be more local in its nature than other cancers—that is, a complete and early removal has not infrequently given the patient a long lease of life. It recurs, as a rule, in the lymphatic glands (which inflame and break down or suppurate) or in the scar; and generally proves

fatal from the constitutional disturbance which these local manifestations give rise to. Later, but more rarely, it may appear in the internal viscera, bones, &c.

IV. Cylindrical Epithelioma.—The cylindrical epithelioma—badly named adenoid or glandular cancer—is specially the cancer of the alimentary mucous membrane, but may occur in the bladder and elsewhere.

Naked-eye appearances.—To the naked eye it forms at first a prominent tumour in the interior of a viscus, which has a tendency, like other cancers, to ulcerate and involve surrounding tissues, so that the mass may reach an enormous size, and may even make its appearance through the skin. To the naked eye a section is generally whitish and has a granular appearance, which is given to it by the tubules of which it is made. It frequently causes death by obstruction of the bowel; but if it last sufficiently long, it recurs in the lymphatic glands, and then in the viscera and other parts of the body. It is not unusual to find recurrences in the liver with little if any implication of lymphatic glands. The recurrence reproduces precisely the structure of the original tumour.

Microscopical appearances.—Cylindrical epithelioma consists essentially of irregular tubules lined with columnar epithelium in one or more layers, which are the much overgrown crypts of Lieberkühn: it differs in microscopical structure from simple papilloma of the digestive tract only in the greater irregularity of the cells and in the larger proportion of connective-tissue stroma between the tubes. Compare figs. 4 and 5.

V. Colloid Cancer.—Colloid cancer, named from its jelly-like appearance, has given rise to much discussion in reference to the question whether it is developed originally in its mature form, or whether it results from the degeneration of one of the varieties of cancer already described. The latter view is that most widely held, though it must be allowed that epithelioma seldom degenerates in this way, and also that the colloid change usually takes place *pari passu* with the growth of the tumour.

Seat.—Colloid cancer is found most frequently in the abdominal viscera and peritoneum, but may occur elsewhere, as in the breast. Its malignancy is great, but is shown chiefly by the rapidity with which it involves surrounding tissues; it thus forms primary tumours of enormous size, but as a secondary growth is less common; it does, however, occur in lymphatic glands and other parts. It causes death in most cases by interference with the functions of the organs attacked.

Naked-eye appearances.—Colloid cancer consists to the naked eye of a mass of semi-transparent jelly, varying slightly in colour, but mostly pale yellow: this is intersected by delicate white fibrous bands, forming alveolar spaces of different sizes, visible to the naked eye. The consistence of the growth depends upon the relative proportions of these two constituents.

Microscopical appearances.—The bands are found to be actually fibrous; the contained jelly is arranged in concentric laminae between which are minute granules, and in the centre of which is a granular mass, sometimes quite indefinite, but often showing clearly that it consists of the remains of altered cells. These cells are seen in the more recent parts of the growth to be the subjects of

colloid degeneration. The source of the colloid material must be considered still undecided; that some of it is formed by the cells is certain, but it is not equally clear whether the stroma takes any share in its deposition. See fig. 6.

R. J. GODLEE.

CANCERUM ORIS (*cancrum*, a sore; and *oris*, of the mouth).—SYNON.: Gangrenous Stomatitis; Noma; Water-canker; Fr. *Nome*; Ger. *Wasserkrebs*.

DEFINITION.—A rapidly progressive gangrenous ulceration of the cheek, gum, and lip.

ÆTIOLOGY.—Cancrum oris is usually seen in ill-fed, ill-tended children, living under the most faulty hygienic circumstances. It frequently ensues upon some acute degenerative illness, especially measles (110 times in 226 cases—Sannée). Occasionally two or three cases occur together in a school, suggesting the possibility of contagion. Lingard has demonstrated long threads of small bacilli in the spreading edge of noma in man, and in a similar disease of calves; and inoculation on calves of a pure culture from man induced the disease.

SYMPTOMS.—Cancrum oris commences on the inner surface of the cheek, often near the angle of the mouth, or upon the gum; and at this stage some superficial ulceration will usually be found here—that is, ulcerative stomatitis. The disease rapidly advances. The cheek becomes much swollen, raw, shining, and red; a livid spot appears in the centre, and here a spreading black slough forms, while the surrounding parts become purplish or mottled. If the patient can open his mouth sufficiently, the gums will be seen to be red and spongy, ulcerating, or sloughing; even the tongue may show some destruction. The cheek is lined with a tough, adherent, greyish-yellow or soft purplish slough; the jaw may be laid bare, the teeth loosened, and portions of the alveolus necrosed. The breath is very foul, and the flow of saliva is excessive and fetid. Fever may be moderate or high. Pain is slight or absent, and the child, though lethargic, is conscious almost to the end. Not more than one in twenty cases recovers, death being generally due to septic broncho-pneumonia.

DIAGNOSIS.—Formerly mercurial stomatitis sometimes ran on to gangrene in debilitated patients; this inflammation was general, and affected the tongue markedly. No hard line can be drawn between ulcerative stomatitis and noma.

TREATMENT.—This consists in complete and careful excision by knife and sharp spoon of the diseased area, regardless of the deformity which must result. To parts which cannot be excised, nitric acid or pure phenol should be freely applied. Iodoform-gauze is the best dressing. The mouth must be frequently and carefully syringed and sponged out with an antiseptic lotion, especially before food is taken. As far as possible, the child should lie so that foul saliva &c. may dribble from the mouth and not down the throat. Goodhart thinks that even tracheotomy might be done to prevent inhalation of septic material into the lungs. Fluid food, especially pancreatised beef-tea or milk-gruel, should be given regularly and frequently, by mouth, nasal tube, or enemata. Ammonia and bark or other tonics should be exhibited. In cases in which recover some plastic operation will be required.

STANLEY BOYD.

CANITIES (*canus*, hoary or grey-haired).—Whiteness or greyness of the hair. See HAIR, Diseases of.

CANNABIS INDICA Habit.—See DRUG-HABITS.

CANNES, in France, on the Mediterranean coast. A dry, bracing, fairly mild winter climate. Exposed to N.W. Abundant accommodation, both near and at some distance from the sea. See CLIMATE, Treatment of Disease by.

CANTHARIDES, Poisoning by.—SYNON.: Fr. *Empoisonnement par la Cantharide*; Ger. *Cantharidenvergiftung*.

Cantharides, the so-called Spanish Fly, owes its poisonous properties to the presence of *cantharidin*, a non-alkaloidal body. All the preparations of the drug are highly poisonous.

SYMPTOMS.—Soon after taking a poisonous dose of cantharides, the patient is seized with burning pain in the pharynx, and a sense of constriction in the œsophagus. The pain soon extends to the abdomen, and vomiting ensues; the abdominal pain becomes aggravated; and usually purging sets in. The stools are numerous, often scanty, passed with great pain and straining; they are at first mucous, and finally bloody. If carefully examined, little iridescent specks—portions of the elytra of the beetle—may be observed in the fæces and vomited matters. These are of course only observable when the powdered insect has been taken; and they frequently escape observation. Up to this period of the case, should portions of the beetle not have been detected, there is nothing to distinguish the case from one of ordinary irritant poisoning; except, perhaps, that salivation and swelling of the salivary glands are usually prominent symptoms. The gastrointestinal inflammation may be so intensely and rapidly developed, that death may occur from collapse before strangury, the diagnostic symptom, is set up. Generally, however, the course is somewhat different, genito-urinary irritation and inflammation setting in; the symptoms of which are aching pains in the lumbar region, frequent desire to micturate, with violent tenesmus of the bladder, till eventually a few drops of albuminous or bloody urine only can be passed, or none at all. Priapism, erotic excitement, and swelling of the genitals are of frequent, though not of constant, occurrence. Delirium, tetanic convulsions, or paraplegia, may be noted in some cases. Eventually the intolerable agony gives way to collapse, stupor, coma, and death. Abortion not infrequently occurs in pregnant women, the drug being formerly much used as an abortifacient.

DIAGNOSIS.—The intense strangury, the swelling of the genitals, and the bloody stools, will leave little or no doubt as to the nature of the case; and the presence of particles of the drug in the ejecta will be conclusive.

Fatal dose.—Less than half a drachm of the powder, and an ounce of the tincture, have alike proved fatal.

TREATMENT.—Evacuation of the stomach by the use of the stomach-pump, syphon-tube, or an emetic is the first indication in poisoning by cantharides. It is best to thoroughly wash out the stomach. Mucilaginous drinks, white of egg (not the yolk), and demulcents, may be freely given; but oil in any form is to be avoided, as tending to dissolve cantharidin. Opium by the mouth or rectum, or the hypodermic injection

of one-third of a grain of morphine is advisable. Leeches to the region of the bladder, warm fomentations, and warm sitz-baths may afford relief. Chloral hydrate should also be given or the patient kept cautiously under the influence of chloroform. Collapse may be met by ammonia and other stimulants. The hypodermic injection of ether is useful. There is no known antidote for cantharidin.

CAPE OF GOOD HOPE.—A warm, generally dry climate, but very variable, and liable to sudden storms. *See* SOUTH AFRICA; and CLIMATE, Treatment of Disease by.

CAPILLARY BRONCHITIS.—Inflammation involving the minute bronchial tubes. *See* BRONCHI, Diseases of.

CARBOLIC ACID, Poisoning by.—*See* POISONS.

CARBONIC ACID, Poisoning by.—The inhalation of carbonic acid causes injurious or fatal results, according to the length of time and degree of concentration. Carbonic acid accumulates in large quantities, almost undiluted, in pits, cellars, wells, mines (especially after explosions, constituting what is called choke-damp), volcanic grottoes, fermenting-vats, lime-kilns, &c. A continuous contamination of the atmospheric air with carbonic acid goes on from the respiration of animals and the combustion of fuel. The generation of CO_2 by a human being averages about 0.6 cubic foot per hour; that of an ordinary gas-burner 2 cubic feet of CO_2 for every one of gas burnt; that of an oil lamp relatively more. The gradual exhaustion of oxygen and proportionate accumulation of carbonic acid in ill-ventilated apartments is one of the factors of the evil results of bad ventilation, but not the only one, as other animal exhalations contribute largely to the result.

As a rule excess of carbonic acid means corresponding deficiency of oxygen; an atmosphere containing 3 to 4 per cent. produces hyperpnœa, and 10 per cent. cannot be inhaled without causing great distress. Haldane breathed air containing 18.6 per cent. for a minute and a half to two minutes, which caused hyperpnœa, cyanosis, and confusion of mind; such a percentage of carbonic acid, and probably one much lower, could not be long inhaled without causing death. Much less than this causes injurious consequences if long inhaled; and less than 2 per cent. cannot be breathed for any length of time with impunity.

If the amount of oxygen be not correspondingly diminished, carbonic acid, if present in sufficient quantity in the atmosphere respired, will still act fatally. Thus Bernard found that a bird died instantaneously in an atmosphere of equal parts of oxygen and carbonic acid; and Snow found that 20 per cent. of carbonic acid in an atmosphere containing the normal proportion of oxygen soon proved fatal to small animals, and that even 12 per cent. might cause death after a longer interval.

SYMPTOMS.—Undiluted carbonic acid is not readily inhaled, as it tends to induce spasm of the glottis, but immersion in such an atmosphere is rapidly fatal. It seems to act as a narcotic. The patient falls down prostrate and insensible, and death occurs almost immediately. This effect is seen occasionally when labourers incautiously de-

scend an old well, or when miners enter a region filled with choke-damp. Not infrequently several fall victims, as one goes to see what has happened to the other and meets the same fate.

When the carbonic acid is more diluted, the symptoms are headache, giddiness, and sense of oppression, followed by drowsiness, and singing in the ears. Ultimately a condition of insensibility ensues, with stertorous breathing and muscular prostration; death usually occurring quietly and without convulsions. If the excess of carbonic acid coincides with deficiency of oxygen, we have, in addition to the essentially narcotic effects of carbonic acid, the dyspnœa and other symptoms of asphyxia. *See* ASPHYXIA.

POST-MORTEM APPEARANCES.—These are largely those of asphyxia, namely, a general engorgement of the venous system. This is generally seen in the brain, more frequently than in asphyxia pure and simple. The blood is dark and fluid. The hæmoglobin is completely reduced. Animal heat is said to be retained long after death, and rigidity is well marked and enduring.

PATHOLOGY.—As has already been said, carbonic acid does not merely act as a negative asphyxiant by taking the place of oxygen, but has a distinctly toxic narcotic effect. Very frequently in cases of poisoning by carbonic acid there is a combination of asphyxia, essentially due to deficiency of oxygen, with the narcotic symptoms due to carbonic acid.

TREATMENT.—1. *Prophylactic.*—Caution should be exercised in exploring wells, mines, &c., where there is any likelihood of the accumulation of carbonic acid. The introduction of a lighted candle is a rough and ready test of considerable value. The mere fact of a candle continuing to burn in an atmosphere is no test of its being respirable with impunity, for a candle will burn in an atmosphere containing 10 per cent. of carbonic acid if the oxygen is present in the normal amount. If carbonic acid reaches the proportion of 16 per cent. the candle will be extinguished. If a candle is extinguished the atmosphere should be regarded as unsafe. If carbonic acid is present, it should be expelled by creating a draught of some kind. Thus wells may be swept by some such contrivance as an inverted umbrella, and a stream of air or steam can be directed into enclosed spaces.

2. *Restorative.*—Artificial respiration and its various accessories are needed to restore a person actually in a state of coma from carbonic acid. This treatment, of course, is subsequent to instant removal from the impure atmosphere. Pure oxygen should also be administered if at hand. *See* ARTIFICIAL RESPIRATION; and RESUSCITATION.

D. FERRIER.

J. DIXON MANN.

CARBONIC OXIDE, Acute Poisoning by.—On account of its cumulative action, carbonic oxide is a much more dangerous toxic agent than carbonic acid. Pure carbonic oxide is rarely generated out of the chemical laboratory, but it is not infrequently met with in admixture with other gases. The most common sources of carbonic oxide as a poison are:—(1) illuminating gas, whether ordinary coal-gas, which contains from 5 to 8 per cent. of carbonic oxide; or carburetted water-gas, which contains 20 per cent. or more; (2) the fumes given off from burning charcoal, from imperfectly fitted slow-combustion-stoves, from brick-kilns, from certain ex-

ploives used in mines, and from the combustion of inflammable materials in the interior of buildings which are on fire.

The toxic effects produced by carbonic oxide are determined by two conditions: the percentage of the gas present in the atmosphere which is inhaled, and the duration of the inhalation. From experiments made on himself, Haldane came to the conclusion that 0.05 per cent. of carbonic oxide in otherwise normal air produces distinct toxic symptoms in man, and that 0.2 per cent. causes urgent symptoms. One per cent. is usually accepted as a fatal admixture. A concentrated atmosphere of carbonic oxide rapidly causes death; a more dilute atmosphere of not less than 1 per cent. is equally fatal if the period of inhalation is prolonged.

PATHOLOGY.—The powerful toxic action of carbonic oxide is due to its affinity for hæmoglobin, which is 140 times greater than the affinity of oxygen for hæmoglobin; the consequence is that when carbonic oxide is inhaled it displaces the oxygen of the hæmoglobin and forms carboxyhæmoglobin, which is a much more stable compound than oxyhæmoglobin. Blood thus changed is unable to take up oxygen; consequently internal respiration is arrested and death takes place from asphyxia.

Carboxyhæmoglobin is bright red in colour and yields a two-banded spectrum like that of oxyhæmoglobin, except that the bands are slightly nearer the violet end of the spectrum (*see SPECTROSCOPE IN MEDICINE, Plate*). A reducing agent such as ammonium sulphide, which changes the spectrum of oxyhæmoglobin to that of reduced hæmoglobin, produces no alteration in the spectrum of carboxyhæmoglobin; in other words, carboxyhæmoglobin is irreducible, which accounts for the blood retaining its bright colour, although death is due to asphyxia. Death usually occurs before the whole of the hæmoglobin is converted into carboxyhæmoglobin, and recovery is possible if there is enough free hæmoglobin left to carry on internal respiration until the carbonic oxide is dissociated from the rest of the hæmoglobin; for, although a stable compound, carboxyhæmoglobin passing through lungs respiring pure air tends slowly to part with its carbonic oxide, the hæmoglobin thus liberated regaining its oxygen-carrying function.

SYMPTOMS.—A sensation of heaviness in the head, dizziness, noises in the ears, oppression in the chest, vomiting, muscular feebleness, followed by complete relaxation of all the muscles, including the sphincters, drowsiness merging into coma, hyperæmic conjunctivæ, dilated insensitive pupils, cold surface, small thready pulse, and frequently froth on the lips, are the chief results of a fatal dose of carbonic oxide. Convulsions and vomiting not infrequently precede death.

POST-MORTEM APPEARANCES.—*Externally.*—The appearance is very characteristic: the whole body is more or less light red in colour, almost the colour of a child with scarlet fever; the *post-mortem* stains, instead of being dull red or slate-coloured, are a bright pink. Cadaveric rigidity is well marked and passes off slowly.

Internally.—The blood is cherry-red in colour and is fluid; the viscera generally are much lighter in colour than is usual, especially the intestines, which are characteristically pink. The lungs may be œdematous, and the trachea and bronchi may contain froth. The blood and the tissues resist putrefaction for a very considerable time.

Carboxyhæmoglobin may be recognised by its spectroscopic appearances. Any hæmoglobin, however, which remains free undergoes reduction as usual, the result being that the persistent bands of carboxyhæmoglobin are superimposed on the broad band of reduced hæmoglobin. If some of the blood in a test tube be diluted with 20 times its volume of water, and an equal volume of a solution of sodium hydrate (sp. gr. 1.34) be added, a bright red colour is produced; normal blood similarly treated yields a dirty brown colour.

TREATMENT.—The elimination of the poison is effected through the lungs; but, the process being slow, prolonged artificial respiration is required, along with the inhalation of oxygen. External warmth should be maintained and stimulants administered, either brandy by rectal injection or other subcutaneously. Bleeding to a limited amount, followed by transfusion of defibrinated human blood, has occasionally proved successful.

J. DIXON MANN.

☒ CARBONIC OXIDE, Chronic Poisoning by.

Cases of chronic poisoning by carbonic oxide may occur among individuals who work for long hours in imperfectly ventilated rooms heated by slow-combustion stoves; among furnacemen and stokers; among workmen engaged in the production of water-gas; and, since the introduction of water-gas as an illuminant has become so common, in ordinary dwelling-houses where there is very slight leakage from the gas-fittings.

SYMPTOMS.—The early symptoms are headache, neuralgic pains, anæmia, breathlessness, along with general indications of defective nutrition. Later on peripheral neuritis may supervene.

TREATMENT.—Removal from the influence of the poison with general symptomatic treatment will fulfil all the indications.

J. DIXON MANN.

CARBUNCLE (*carbunculus*, a small coal—*carbo*).—**SYNON.** : Fr. *Anthrax*; Ger. *Karbunkel*.

DEFINITION.—A carbuncle is an inflammatory swelling of variable size commencing in the pilo-sebaceous follicles, spreading into the adjacent skin and subjacent subcutaneous tissue, and causing gangrene of a part of the above structures. It is accompanied by general symptoms which are often serious. A carbuncle is essentially an accumulation of boils aggregated together and complicated with local inflammation of the subcutaneous tissue.

ÆTIOLOGY.—Carbuncles are more commonly met with in the male sex and in old age; they are rare in infancy and childhood. Local irritation plays an important rôle. A carbuncle may originate in a furuncle, especially in cachectic states. Cachexia predisposes to carbuncle by lowering the resistance of the tissues to invasion by the *Staphylococcus pyogenes aureus*. Fatigue, over-indulgence in alcohol, and Bright's disease are predisposing causes. The chief predisposing cause, however, is diabetes mellitus. Indeed the diabetic condition is often first discovered on testing the urine for sugar in a patient suffering from carbuncle. It must be remembered, however, that temporary glycosuria may be associated with a carbuncle.

SITE.—Carbuncles may be found on any part of the body, particularly where the skin is thick, as on the nape of the neck and the back. Carbuncles are generally single, but they are frequently sur-

rounded by a circle of daughter-furuncles due to infection with staphylococci contained in the purulent discharge.

SYMPTOMS.—Malaise, anorexia, headache, and slight febrile disturbances may precede the discovery of any local lesion. In a short time, however, a swelling, acutely painful on pressure, dusky-red in colour, and of brawny hardness, is seen in the skin. At first this swelling presents the appearance of a large boil, but it increases more rapidly in size and prominence while a purplish hue develops in its centre. A little later, vesicles appear on the surface; these contain blood-stained serum, but this is quickly replaced by pus. The pustules rapidly burst, and the true skin is thus exposed, dotted with yellowish purulent spots which soften and leave orifices honeycombing the skin and discharging pus. At the bottom of these openings a greenish-white slough is generally visible. Pain is a nearly constant symptom. It is usually lancinating and frequently so severe as to prevent sleep, thus markedly aggravating the patient's condition.

VARIETIES.—Two distinct types of carbuncle may be described:—(1) Small or medium-sized circumscribed carbuncles.—These vary in size from that of a grape to that of a small orange; they have a well-defined margin and the sloughs usually separate in small shreds. With the separation of the sloughs the gangrenous process ends and healing commences, the malaise and fever rapidly disappearing.

(2) Large diffuse carbuncles.—These indicate a condition of extreme gravity and are accompanied by severe local symptoms and marked constitutional disturbance. From the first there is no tendency for the carbuncle to become defined, as in the more benign form. It seems to be constantly extending its periphery, continuously invading the neighbouring structures. Such carbuncles may cover a superficial area of 100 to 150 square inches, and may thus involve the greater part of the back, reaching, in extreme cases, from the occiput to the lumbar region, and laterally from one acromion process to the other. Even after the greater part of the slough has been discharged spontaneously, or has been removed surgically, extension of the infective process may still occur at the periphery of the carbuncle. In such cases, huge sloughs, consisting of subcutaneous tissue and even in some cases pieces of deep fascia, may be extruded through the crater-like opening. The deep fascia, however, generally forms an efficient barrier restraining the further spread of the disease. In these diffuse carbuncles the temperature may range from 104° to 105° F. Drowsiness and coma or delirium are not infrequent. In the worst cases pyæmia or septicæmia may supervene.

Not infrequently, even after the separation of the slough, death results from the prolonged suppuration and exhaustion. Large sloughs require many days to separate spontaneously, and the healing process is at best slow and tedious. Six weeks to four months, according to the size of the carbuncle, will be required before the healing process is complete. When, however, healing has taken place, the resulting scar is generally much smaller than would have naturally been anticipated.

The carbuncle commonly met with in diabetic subjects is of the gravest danger. It is generally of the large diffuse variety; its onset is sometimes gradual and insidious; and, even when the swell-

ing is very large, the fever and pain are generally only moderate in degree. The gangrenous and ulcerative processes are always extensive, and continuous infection of the margins of the carbuncle is frequently seen. Healing either does not take place or is very much retarded.

Among the most frequent complications may be mentioned erysipelas, infective spreading cellulitis, septic phlebitis (especially serious in carbuncle of the face), and suppuration either around or underneath the carbuncle, or in other parts of the body (pyæmic abscess).

PROGNOSIS.—This depends upon the nature of the lesion, whether small and circumscribed, or large and diffuse; upon the presence or absence of complications; and very largely upon the general condition of the patient and the existence of any of the predisposing causes.

The mortality in small circumscribed carbuncles, in the absence of any dyscrasia and of any complications, is low; but it is quite otherwise in large diffuse carbuncles. In these the mortality is at least 10 per cent. in non-diabetic cases, and 35 per cent. in those suffering from diabetes. In the markedly gangrenous type occasionally met with in diabetics, death results almost invariably.

DIAGNOSIS.—In its early stages a carbuncle may be mistaken for a boil, and indeed often commences as such. The essential difference between the two conditions is that the inflammatory induration is subcutaneous in a carbuncle, not purely cutaneous as in a furuncle.

TREATMENT.—*General.*—To combat the pain and to enable the sufferer to obtain sleep, opiates are generally necessary.

In diabetics codeine in doses of half a grain every six hours is preferable to opium. During the febrile stage ample fluid nourishment, e.g. milk, chicken-broth, meat-essences, and gruel, must be given, and these should be peptonised if digestion is much impaired. During the separation of the sloughs and the healing of the resulting surface tonics and generous diet are required. When the patient is passing into a poisoned adynamic condition, liberal stimulation with alcohol is urgently called for. Alcohol, however, is best avoided in the early febrile painful stage, as it generally increases the sufferings of the patient.

Local.—In the early stages abortive treatment may be tried, but owing to the inflammatory process having its seat largely in the subcutaneous tissue, abortive treatment is not nearly so effectual as in furunculosis, in which the condition is purely cutaneous. Good results are, however, generally obtained by smearing the surface of the inflammatory swelling with the following ointment: *R*, acidi carbonici cryst. gr. xx, extract. ergotæ liquid. ʒj ss, zinci oxidi ʒj ss, lanolin ad ʒj. Even if this fail, as it generally does, to arrest the carbuncle, it lessens the pain and inflammatory congestion (see BOILS). Warm antiseptic fomentations may also be employed. The application of caustics is always to be condemned.

The local surgical treatment of the majority of carbuncles, in which it is clear that suppuration has occurred or is about to occur, consists in either *excision* or *incision*.

Excision may be employed for circumscribed carbuncles not exceeding an orange in size. An oval or circular incision is made outside the diseased margin, and the mass is dissected out down to the deep fascia. The risk in this opera-

tion is that of infection of the wound ; hence it is essential that the mass be not burst or cut into during the excision, and that the raw surface be painted with a strong antiseptic, preferably with liquefied pure carbolic acid. An antiseptic dressing is then applied, and later on skin-grafting after Thiersch's method may be necessary. Little loss of tissue is occasioned by excision, as the greater part of the skin and subcutaneous tissue removed would in all probability have sloughed. The advantage of the method is that in successful cases, i.e. those in which infection of the raw surface is avoided, the pain disappears at once and the patient is saved from the suppuration and risk of septic complications which a carbuncle frequently entails.

Incision, preferably combined with the cutting away and curetting of all the infected and sloughy tissues, is the method of treatment commonly adopted in all large carbuncles, and in those of medium size which are not well circumscribed, i.e. have no definite indurated margin.

The incisions may be crucial or multiple according to the dimensions of the carbuncle. They must in all cases extend to the extreme periphery of the carbuncle and traverse the entire depth of the infected area. Incision alone relieves tension and facilitates the discharge of pus and sloughs, but it should be in all cases combined with the removal of the sloughs and infected honeycombed skin. This removal is often a tedious matter, but by the use of scissors and curette the entire necrotic tissue can generally be removed. The bleeding may be free, but is always arrested by pressure. The large raw wound must now be freely painted with pure carbolic acid and stuffed with antiseptic gauze wrung out of 1 to 30 carbolic solution or 1 to 2,000 biniodide of mercury lotion. Until the wound has cast off all its slough and has assumed a clean granulating appearance, it is necessary to dress it daily with gauze and to wash the surface with an antiseptic solution. To hasten the process of cicatrization, skin-grafting by the method of Thiersch will frequently be found necessary.

In certain cases of carbuncle, in which the general symptoms are very slight and the pain is very moderate, no operative treatment is called for ; the carbolic acid and ergot ointment, or hot antiseptic fomentations, may be applied, and the carbuncle allowed to extrude its sloughs spontaneously. Carbuncles on the face, owing to the gravity of the complications (septic phlebitis, meningitis, orbital cellulitis, &c.) which frequently attend them, call for immediate incision and disinfection of the purulent focus of infection (*see BOILS*).

HERBERT F. WATERHOUSE.

CARCINOMA.—*See* CANCER.

CARDIAC DISEASES.—*See* HEART.

CARDIALGIA (*καρδία*, the heart ; and *ἄλγος*, pain).—A synonym for heartburn, originating in a popular impression that this painful sensation, which starts from the epigastrium, is connected with the heart. *See* HEARTBURN.

CARDIOGRAPH (*καρδία*, heart ; and *γράφω*, I write).—This is an instrument for recording the impulse of the heart against the chest-wall. The graphic tracing so obtained is known as a *cardiogram*. Chauveau and Marey introduced this method

of observation in 1861. The principle is as follows : a small button applied over the so-called apex-beat transmits the variations of pressure which it receives to the rubber membrane of a small air-tight capsule. This receiving tambour, as the capsule is called, is connected by rubber-tubing to a recording tambour, upon the rubber-membrane of which is attached a lever. Every movement of the button is thus transmitted by the air enclosed in the apparatus to the lever, which records the magnified movement upon the smoked paper of a revolving cylinder.

In France the term 'cardiograph' is applied also to a form of the instrument so modified that the small recording tambour can be introduced through the carotid artery or the jugular vein of a horse or dog, into the aorta and left ventricle, or into the right auricle and right ventricle, as the case may be. The graphic records of the pressure in these different chambers of the heart are of value in the interpretation of the tracing obtained with an ordinary cardiograph applied to the chest-wall.

The curve obtained with the cardiograph has been the subject of much discussion, but most authorities give a curve similar to fig. 1. It consists of (1) a very steep ascending limb, (2) a plateau with three small waves, and (3) a very steep descending limb. The slight undulation *a-b* is due to the contraction of the auricles forcing blood into the ventricles. The steep ascent *b-c* is caused at its beginning by the filling, and then by the contraction of the ventricles, which is maintained until *e*, when the aortic and pulmonary valves are closed. The steep descent *e-f* is due to the relaxation of the ventricles. The opening of the sigmoid valves occurs according to some authorities at the point marked *, according to others at *c*. The first sound of the heart begins soon after the rise at *b* ; the relation of the second sound to the cardiographic curve is doubtful : some state that it begins at *e*, others at *f*. The cause of the undulations upon the systolic plateau *c-e* is uncertain, but they are not due to imperfections in the recording instrument. Roy and Adami think that they are caused by a want of synchronism in the contraction of the different parts of the ventricle. Marey holds that they are due to retrograde waves from the aorta towards the left ventricle.

FIG. 1.—Curve of the impulse of the heart of man (after Marey)

The cardiogram is a complex curve ; it represents not only changes due to the contraction of the cardiac muscle, but also changes in the ventricular blood-pressure and in the volume of the heart. Further, it is necessary to remember that the position of the heart in relation to the chest-wall varies during the different phases of the cardiac cycle, and that the resistance and thickness of the intercostal spaces differ even in healthy subjects.

According to Marey and his followers the cardiogram is a curve of the intra-ventricular pressure, but this view has been contested by many physiologists and physicians in this country and in Germany.

The practical value of the cardiograph in clinical medicine is very limited, and it must be confessed

that the tracings obtained by its use are liable, owing to the difficulties of interpretation, to lead to erroneous conclusions. Further, there are great difficulties in obtaining typical tracings even in perfectly healthy men; in many cases, owing to the conformation of the chest, the development of muscle or adipose tissue, or extensive overlapping of the lung, the apex-beat is obscured and does not give sufficient impact to yield a typical curve. Another source of difficulty often experienced is the movement of the chest-wall in respiration. Roy and Adami state as the result of their numerous experiments that 'the cardiographic curves from man have not as yet been found fitted to give much information regarding the action of the heart either in health or in disease.'

The chief value of the cardiograph is in the determination of the beginning and end of the ventricular systole. It can also be used for recording the pulsation of aneurysms, and for this purpose it is sometimes advisable to replace the receiving tambour by a glass funnel, which can be pressed down upon, and made to enclose the area of skin under which the pulsation is observed.

M. S. PEMBREY.

CARDIOLITH.—See CONCRETIONS.

CARIES (*caries*, rottenness).—A destructive inflammatory disease of bone, analogous to the ulceration of soft tissues. See BONE, Diseases of.

CARLSBAD, in Bohemia.—Thermal alkaline sulphated waters. See MINERAL WATERS.

CARMINATIVES (*carmino*, I card, or cleanse). DEFINITION.—Substances that aid the expulsion of flatus from the stomach and intestines, and relieve griping.

ENUMERATION.—The principal carminative remedies are—the Essential Aromatic Oils, for example, Peppermint and Cloves; Chloroform; Charcoal; Ethers; and Camphors, and substances containing them.

USES.—The uses of carminatives are sufficiently indicated in the preceding definition. They are extensively administered in cases of flatulent dyspepsia, especially when it is associated either with disease or disorder of the heart, or with a nervous or hysterical state of the system. A combination of several different carminatives is usually more successful than the exhibition of a single drug, one of the best being a mixture containing Spirit of Ether, Aromatic Spirit of Ammonia, and Tincture of Orange. Given along with antacids they are useful in correcting acidity, as in the favourite Soda-mints; and they are frequently prescribed with purgatives to prevent pain—an application illustrated by the official Compound Rhubarb Pill.

T. LAUDER BRUNTON.

CARNIFICATION (*caro*, flesh; and *fio*, I become).—A condition of the lung in which it resembles flesh. The term was formerly applied to the transformation of any tissue into a flesh-like substance. See LUNGS, Collapse of.

CARPHOLOGY (*κάρφος*, chaff; and *λέγω*, I collect).—The movements of the hands and fingers observed in certain delirious patients, as if they were searching for or gathering imaginary objects. A familiar illustration of the act is 'picking of the bedclothes.' See TYPHOID FEVER.

CARPO-PEDAL CONTRACTIONS.—See TETANY.

CARRION'S DISEASE (*Verruga Peruana*).—This name is applied to a remarkably infectious disease, usually characterised by the formation of multiple granulomatous tumours on the skin. Its course in such cases is chronic or subacute, but it may also run an acute course and frequently terminate fatally.

At present it has been mentioned as occurring only in the moist valleys of the Andes of Peru, at an altitude of from one thousand to three thousand metres. On the Oroya Valley Railway Extension, 50 per cent. of the engineers and 75 per cent. of the European navvies died of the disease. The disease appears to be very strictly limited to these localities.

Three clinical types are described: the simple eruptive form, the rheumatic form, and an acute form which may kill the patient in a few days, before the eruption has had time to appear. The last type has also been described as Oroya Fever. The identity of the chronic verrucous form and Oroya Fever was established when Daniel Carrion, a Peruvian student, inoculated himself with *verruca*, the lesion of the chronic type, and died in nineteen days from the acute form of the disease.

Careful investigations have been carried out both in the benign and in the malignant types of the disease. Several organisms have been described in the wartlike granulomata, but no specific organism has yet been isolated.

This malady affects persons of all ages; and animals, such as mules, suffer from a slightly specialised form of the disease.

JAMES GALLOWAY.

CARTILAGE, Diseases of.—SYNON.: Fr. *Maladies du Cartilage*; Ger. *Knorpelkrankheiten*.

Cartilage being generally non-vascular, its inflammation is of a modified type, and may present degenerative changes as the result of impaired nutrition. In uncomplicated disease of cartilage there is no inflammatory exudation, and when lymph or pus is found in a joint, it is obvious that other structures have become inflamed. In those cartilages in which vessels are found, e.g. rib-cartilages, true central inflammation may occur. When cartilage has been destroyed it may be replaced by fibrous tissue or bone, but it is never reproduced.

1. The ensiform and costal cartilages, with those of the trachea and larynx, show a great tendency to *ossification*, as the result of senile changes; they are also liable to *necrosis*. The articular cartilages never ossify, but large or small portions of them may perish and be detached, in consequence of some interference with their supply of nutriment from the subjacent bone. In pyæmic joint-effusions the cartilage softens, and is rubbed off the most prominent portions of the articular surfaces in a manner quite characteristic. In osteo-arthritis, one of the earliest of the pathological changes occurs in the articular cartilage. The cells proliferate, the primary capsules enlarge and fill with secondary capsules, and the matrix fibrillates and softens. By degrees the cartilage is worn off the central part of the articulation, exposing the bone underneath; laterally, where the pressure and friction are less, the cartilage-cells proliferate and form a tuberculated margin, which subsequently ossifies.

2. The cartilages of the epiglottis, ears, nose, eyelids, and Eustachian tube are liable to *ulceration*, especially of the syphilitic variety; in these cases the disease commences in the skin or mucous membrane, and spreads to the cartilage by contiguity.

3. The cartilage of the external ear is often the seat of 'chalk-stones' in gouty persons, and similar *deposits of urate of sodium* are found in the articular cartilages.

4. The epiphysal cartilage may be the seat of *inflammatory changes*, generally very acute, which lead to separation of the shaft from the epiphysis, a condition which, whether the result of disease or accident, is of great moment, inasmuch as the destruction of this layer of cartilage may check further growth at this end of the bone.

Epiphysitis may occur as a primary disease: in other cases inflammation may spread from the extremity of the diaphysis. Syphilis, especially of the inherited form, is the most common cause of this disease. Injury, particularly in strumous children, is also a factor in its production. The acute form is often associated with general septicæmia, and is followed by destructive changes in the adjacent joint. In children who suffer from the syphilitic form of the disease, the joint is generally preserved and the subsequent growth of the bone little impaired.

5. Cartilage is not primarily attacked by *cancer*, but it may become involved by the spread of a malignant tumour. The *epithelial* form of cancer not infrequently extends from the mucous or cutaneous surface, in which it originated, to the subjacent cartilage.

6. The articular cartilages are liable to certain structural changes as the result of disturbed nutrition; and the fibro-cartilages are also subject to the same abnormal conditions.

Ulceration, absorption, degeneration of cartilage, are terms used to denote a series of destructive changes which take place in the substance of articular cartilage, and lead to its partial or complete removal. These changes may originate in the cartilage itself, or they may be secondary to disease of the bone or synovial membrane; however this may be, the morbid action is the same, and consists in increased cell-development, with disintegration of the hyaline substance. The cartilage-cells become enlarged, filled with nucleated corpuscles, and arranged irregularly. The matrix softens; and in acute cases rapidly disintegrates and is discharged: when the disease is more chronic, it splits up into fibres which remain attached by one end to the cartilage, and at the other project loosely into the interior of the joint, giving a villous appearance to the affected spot. The remains of the cartilage are ultimately converted into fibrous tissue, and constitute the sole medium of repair when a cure is effected. The different appearances which the affected cartilage presents under different circumstances have led to the several terms *fibrous*, *fatty*, and *granular degeneration* being applied to this disease, in the belief that they were really distinct pathological conditions. Changes of this kind may be primary, as in osteo-arthritis, but they are commonly secondary to disease in the articular ends of the bones, the result of syphilis, tuberculosis, or injury. See JOINTS, Diseases of.

W. MAC CORMAC.

W. CECIL BOSANQUET.

CASEATION (*caseus*, cheese).—This name is applied to a peculiar process by which masses of tissue are converted into a yellowish-white, pulpy material, somewhat resembling cream-cheese. It is seen chiefly in tubercular foci, but a similar degeneration is met with in the central portions of gummata, and in nodules of carcinoma and sarcoma: it may also be found in connection with some of the rarer irritant organisms, such as the actinomyces, the bacillus of pseudo-tuberculosis, and certain moulds (aspergillus). The tubercle-bacillus appears to secrete a peculiar acid substance which has the power of causing necrosis of tissues: the process is assisted by the tendency to fatty degeneration that exists in the centre of a tubercular mass, owing to the blood-supply being cut off by contraction of the fibrous tissue formed around it. The occurrence of caseation in individual tubercles before fibrosis has occurred, shows that the action of this latter cause is not indispensable. In gummata the nutrition of the central portions is defective owing to narrowing of the blood-vessels by syphilitic endarteritis. In tumours the growth of cells is so rapid that the mass outgrows its blood-supply, while it is possible that the cells thus rapidly and irregularly formed are themselves of deficient vitality. The affected cells become first granular, then fatty, and finally all structure in the part is lost and the tissue is converted into a mass of soft amorphous debris. At the periphery of the caseous portion some free nuclei may be seen lying amidst the degenerative products, since these bodies resist the process of disintegration longer than the protoplasm of the cells. The caseous material consists of fatty granular particles, leucocytes, cholesterin-crystals, and a certain amount of fluid exuded from the lymphatics. The fate of caseous foci varies: in some instances they dry up and become infiltrated with calcium-salts, giving rise to masses of stony hardness; in others softening occurs and the caseous mass is converted into a milky fluid somewhat resembling pus. Cavities filled with this material are known as *chronic* or *cold* abscesses. Caseous masses are frequently met with in the bronchial, mesenteric, and cervical lymphatic glands, and in the lungs, brain, and bones. In the great majority of cases they are due to tuberculosis, but the existence of caseation is not by any means pathognomonic of lesions due to this cause.

W. CECIL BOSANQUET.

CASTS (derived from the Middle English word *casten*, which is adapted from the Old Norse *kasta*, to cast or throw).—SYNON.: Fr. *Cylindres*; Ger. *Cylindern*.

DEFINITION.—A term applied to moulds of gland-tubules and hollow viscera thrown off in certain states of disease.

CLASSIFICATION.—The varieties of casts met with may be thus grouped:—

A.—CASTS OF GLAND-TUBULES.

- | | |
|-------------------------------|-------------------|
| I. Of the Uriniferous Tubules | Blood-casts. |
| | Leucocyte-casts. |
| | Epithelial casts. |
| | Granular casts. |
| | Fatty casts. |
| | Waxy casts. |
| | Hyaline casts. |
| | Cylindroids. |
| | Bacterial casts. |
| | Pseudo-casts. |

- II. Of the Seminal Tubules.
- III. Of the Gastric Tubules.
- IV. Of the Bile-ducts.
- V. Of the Cutaneous Glands.

B.—CASTS OF HOLLOW VISCERA AND PASSAGES.

- I. Of the Alimentary Canal.
- II. Of the Urinary Bladder.
- III. Of the Female Genital Passages.
- IV. Of the Respiratory Passages.

A.—CASTS OF GLAND-TUBULES.

I. Of the Uriniferous Tubules.—Though it is known that renal casts may be formed in any part of the kidneys, their exact mode of origin is still unsettled. According to one view they are formed by exudation of the blood, and due to the rupture of engorged vessels; according to another by transudation of blood-plasma, which in its passage through the renal epithelial layer undergoes some modification of composition; a third speculation is that they are due to a secretion from the cells of the tubules which have undergone some pathological change; while a fourth ascribes them to a fusing together of degenerated epithelial cells. Thus, in the last two instances the cells are directly, in the second indirectly or less directly, and in the first not at all concerned in the production of casts. It is quite possible, however, that these bodies may be derived in all the four ways; but though it is customary to distinguish several modes of origin it will be found that more than one kind of cast is nearly always present in the same urine, and that different sorts are connected by transitional gradations.

None of these views, however, explains very satisfactorily why casts which give the 'amyloid' reaction may exist alike with and without lardaceous change in the viscera; nor do they account for the presence of hyaline casts in non-albuminous urine and under anephritic conditions. Moreover, there is not complete agreement as to nomenclature; for while some writers distinguish between hyaline, colloid, waxy, fibrinous, and lardaceous casts, holding them to be of different composition and origin, others seem inclined to place all those cylinders having a homogeneous structure and a more or less transparent appearance in one category. The term 'granular cast' is somewhat unfortunate, for it includes casts which are composed of granules (intrinsic granulation) and casts covered with granules (extrinsic granulation). Very similar remarks apply to fatty casts: every kind of cast is prone to exhibit fat-globules, but it is only when they are a very prominent feature that the term 'fatty' becomes an appropriate designation. Practically, however, there is unanimous agreement that casts are indicative of abnormal states of the kidneys, and are therefore of great clinical importance.

In shape renal casts are mostly cylindrical, but not infrequently are bent and occasionally forked. In length they vary considerably: often quite short and stumpy, they not infrequently stretch right across the field of the microscope. In diameter they mostly range between $\frac{1}{1000}$ and $\frac{1}{500}$ inch, the majority being of medium size, i.e. about $\frac{1}{700}$ inch.

Castes are composed of an albuminous or of an albuminoid matrix, within which may be embedded epithelial cells and blood corpuscles, crystals (e.g. oxalates, uric acid), oil-globules, and other particles, and

upon the surface of which may be deposited minute crystals, granular debris, oil-globules, pigment, and cells.

When microscopic sections of diseased kidneys are examined, tubules may be seen to contain red corpuscles, whole or broken up; leucocytes; free epithelial cells, globose and otherwise altered; granular debris and crystals; but more frequently the contents of the tubules are cylinders composed of a homogeneous substance, which in appearance is more or less transparent or faintly granular. These moulds often exhibit colour-reactions similar to those of 'amyloid.' In connection with epithelial casts it may be mentioned that sections of the kidney in acute nephritis do not exhibit the loss of epithelium that might be expected from the ordinary inspection of the urinary sediment, and this leads to the suspicion that many of these cell-casts are really leucocytic. In some cases of nephritis, however, the appearance of some of the tubules, owing to degenerative changes in the epithelium, presents a striking resemblance to granular casts. It is difficult to estimate the value of this observation, and too much importance should not be attached to it. Sometimes one cylinder inside another may be observed *in situ*.

Blood-casts consist mainly of red corpuscles included in a fibrinous basis. They are indicative of acute nephritis (primary or secondary) and hæmorrhagic conditions of the kidney. In hæmoglobinuria casts of disintegrated corpuscles may be present. Blood-casts are of a yellowish colour and often have a coarsely granular appearance. See fig. 1.

FIG. 1.—Blood-casts.

Leucocyte-casts are composed of agglomerations of white blood-corpuscles, and when in the condition known as pus their presence is indicative of a suppurative process, but casts from acute and subacute nephritis frequently contain large numbers of leucocytes.

Epithelial casts are such as contain epithelium from the tubules, and their presence is indicative of a desquamative nephritis. The condition of the epithelial cells is very variable; often of fairly normal appearance, they are sometimes so de-

FIG. 2.—Hyaline casts.

generated that they are scarcely recognisable as such, and rather resemble a cylindrical aggregate of granules of variable size. Many cell-casts which if inspected in the unstained condition present appearances resembling epithelium are really leucocytic. See fig. 3.

Granular casts.—Under this term are included casts which exhibit a finely or coarsely granular

appearance. It includes casts composed of broken-up blood-corpuscles, degenerated epithelial cells, and casts containing fatty globules. A granular appearance is also exhibited when a hyaline matrix is covered with granular debris, minute crystals, fat-globules or crystals. Their diagnostic value is therefore variable and depends on their origin, but in most cases their presence is of unfavourable import and is indicative of nephritis. See fig. 5.

FIG. 3.—Epithelial casts.

Fatty casts are such as contain fatty globules or upon which oily spherules and fat-crystals are deposited. The globules may be few or many and are of variable size. If numerous, the casts have a granular appearance. They are found in subacute and chronic nephritis, and are of unfavourable import when they can be assigned to a condition of progressive deterioration, but on the other hand fatty degeneration in casts may be indicative of resolution. See fig. 4.

Waxy casts, sometimes also called *colloid*, are homogeneous, refracting cylinders frequently of large

FIG. 4.—Fatty casts.

size and sometimes giving the 'amyloid' reaction with iodine and methyl violet. They are most frequent in chronic nephritis where there is much albumen in the urine. The 'amyloid' reaction of these casts, however, is not a sure indication of the lardaceous change in the viscera, for it may be present when there is no lardaceous degeneration, and *vice versa*.

Hyaline casts are highly transparent and but little refractive cylinders of small to medium size. They may be found in most cases of Bright's disease, most

health and of disease, and most frequently in that of children. Whether they are of renal origin is uncertain, and albuminuria does not always accompany them.

Bacterial casts.—Casts consisting of micro-organisms have been met with in septic affections of the kidneys. They are distinguishable from other granular casts by their staining-reactions with aniline dyes, and by the regular shape and size of their constituent elements.

Pseudo-casts.—This term has been applied to certain artificial or accidental aggregates of minute crystals (e.g. urates) or granular debris which from their size and cylindrical shape simulate the appearance of renal casts.

Casts containing hæmatoidin, bile-granules, and indigo are occasionally met with.

CLINICAL SIGNIFICANCE.—In regard to diagnosis and prognosis there are but few considerations which discount the importance of casts in the urine as a criterion of disease of the kidneys. It is true, however, that hyaline casts have been observed in non-albuminous urine after severe physical exertion, in cases of protracted jaundice, in lithuria, oxaluria, and diabetes mellitus. They may occur too in conditions of transitory congestion of the kidneys, and one observer has recorded their appearance after epileptic fits. In instances of this description there may be no other symptoms or evidence to point to organic disease of the kidneys. Such examples are, however, fairly uncommon. As a rule casts are accompanied by more or less albumen, and their presence affords valuable assistance both as regards diagnosis and prognosis. It would not, however, be a warrantable deduction that the gravity of any given case was commensurate with the number of these cylindrical excreta. For in some cases casts are few and the organic change in the kidney is great; and on the other hand they may be many, though the prognosis will be favourable. For example, in advanced contracted granular kidney the casts are often few; in acute nephritis they are often numerous and may even exhibit the appearances of fatty degeneration. It is a question less of number than of kind, though of course numbers are unfavourable where the kinds are indicative of severe and permanent damage. Moreover, the number of casts may have little relation to the quantity of albumen, for the amount of albumen may be large and the number of casts few—a point which has some bearing on the mode of origin of these bodies. It must also be borne in mind that one disease or one kind of morbid change in the kidneys does not produce merely one kind of cast, for in the same urine, whether from acute or chronic nephritis, two or more kinds of casts may be found. So the diagnosis of the present and the prognosis of the future condition of the organs must be made from a sort of rough average struck between the various kinds of casts, their relative importance, and their increase or decrease as time goes on.

It is always necessary to examine the urinary sediment for casts on several, indeed frequent, occasions, not only to be satisfied as to the particular class of cast, but also to ascertain whether they present indications of improvement or the contrary. And in connection with these examinations it may be laid down that for practical purposes casts may be placed in three categories according as they indicate *Acute* or *Chronic* disease or an acute attack

FIG. 5.—Granular casts.

often in contracted granular kidney, but have been observed in non-albuminous urine and under conditions when nephritis could be excluded. See fig. 2.

Cylindroids.—The name 'cylindroids' has been given to certain long, colourless, ribbon-like bodies which may have some resemblance to hyaline casts. They are somewhat irregular in outline, are longitudinally striated, and give the mucin-reaction with acetic acid. They have been found in the urine of

supervening on a chronic condition. The first is characterised by the presence of blood-, epithelial, and granular casts; the second by more or less transparent (waxy, colloid, hyaline), and also by fatty and granular casts; while in the third are found casts typical of the acute and chronic conditions, though those characteristic of the latter usually predominate.

For the method of examination for casts of the uriniferous tubules see URINARY DEPOSITS.

II. Of the Seminal Tubules.—Spermatic casts are largish hyaline cylinders composed of a mucoid matrix and containing spermatozoa. They are supposed to arise from the seminal tubules, and their presence is not necessarily associated with albumen in the urine. They are of rare occurrence, and their pathological significance is doubtful.

III. Of the Gastric Tubules.—In inflammation of the gastric mucosa, especially in scarlet fever, a desquamation of the epithelial coat involving the glands has been observed. The casts of the follicles have been found in the vomit, and more abundantly in the contents of the stomach *post mortem*. Their length is variable, and in width they range from $\frac{1}{1000}$ to $\frac{1}{1000}$ of an inch. Their substance is described as being fibrinous and is covered more or less completely with altered epithelial cells and granular debris.

IV. Of the Biliary Ducts.—In the centre of gall-stones have been found long hair-like threads, often branched and generally under $\frac{1}{200}$ inch in diameter, consisting of mucus, inspissated bile, and epithelium, which have been regarded as casts of the smaller biliary tubes.

V. Of the Cutaneous Glands.—In the various skin-affections which are associated with desquamation of the cuticle, casts of varying length, coming from the sweat and sebaceous glands, are thrown off as part of the general shredding of the epidermis. Such bodies are hollow tubes and bear no resemblance to the renal casts in nephritis.

B. CASTS OF HOLLOW VISCERA AND PASSAGES.

I. Of the Alimentary Canal.—Solid casts of the tonsillar crypts and branches, consisting of inflammatory products, are occasionally expectorated in follicular tonsillitis and diphtheria.

More or less perfect muco-epithelial casts of several inches in length coming from the œsophagus have been met with, and more rarely pieces from the stomach have been detected in the vomit. In cases of corrosive poisoning, should the patient tide over the first effects, more or less complete casts of the œsophagus and stomach may be ejected. Casts of portions of the gullet, formed of dense masses of aphthæ, have also been described.

Intestinal casts and small flocculent pieces from the surface of the colon are far from uncommon, especially in association with chronic constipation. The casts consist of viscid mucus and epithelial cells, matted together into tough coherent pseudo-membranes; they often form complete hollow moulds of the tube, large or small, and vary in length from a few inches to several feet. Occasionally they retain on their surface the impression of the follicles, sacculations, and other inequalities of the intestinal surface.

II. Of the Urinary Bladder.—A complete exfoliation of the mucous membrane of the bladder

has been occasionally observed in puerperal women. It does not appear to be always the result of inflammation, and though detachment may be complete, perfect recovery may follow. In structure such bodies consist of epithelial cells in varying stages of degeneration, felted together by mucus and fine granular material. The surface is frequently thickly coated with urinary salts. The conditions giving rise to their formation are quite unknown, though retention of urine is associated with their occurrence. A few instances of moulds of the ureter and of the urethra have been recorded.

III. Of the Female Genital Passages.—Casts of the uterus and vagina have been frequently noticed. The latter occur as more or less complete hollow moulds of the canal or as membranous plaques of variable size (membranous vaginitis). They are greyish-white in colour, often translucent, are fairly smooth on both sides, and are composed of layers of squamous epithelium. They have been known to follow the use of astringent injections, and cases are recorded of their occurrence at the menstrual periods, and without obvious exciting cause.

Partial casts of the vagina formed of diphtheritic membrane have also been seen.

Uterine casts are of commoner occurrence, and are of various kinds. Exclusive of solid moulds of the cavity, formed of coagulated blood and of fibrin, the states of pregnancy and menstruation are each liable to give rise to the formation of membranous casts of the surface, complete or partial, usually accompanied by much pain in their extrusion (membranous dysmenorrhœa). The membranous cast may be entire, in which case it resembles a triangular bag, measuring from $1\frac{1}{2}$ to $1\frac{3}{4}$ inches in length, by about 1 inch in breadth, and from $\frac{1}{16}$ to $\frac{1}{8}$ inch in thickness. More frequently, however, the membrane comes away in pieces of varying size. The external surface is smooth and the internal somewhat shaggy, and on microscopical examination shows the ordinary structure of the uterine mucosa, in which are plainly visible the characteristic gland-follicles and some blood-vessels. Scattered throughout its texture are often seen leucocytes and small round cells.

Sometimes a uterine cast is the result of an early abortion and may present appearances closely resembling those of a dysmenorrhœal membrane. But in addition to being thicker, microscopical examination may reveal the presence of large decidual cells and chorionic villi. If no villi be found it is not advisable to give a definite opinion as to impregnation, for the large decidual cells are not conclusive evidence.

In extra-uterine pregnancy the membrane is distinguishable from that of membranous dysmenorrhœa by being much thicker and by the presence of large decidual cells; and from that of uterine pregnancy in the absence of reflexa and of amnion.

IV. Of the Respiratory Passages.—In diphtheria a false membrane may be formed on the respiratory mucosa, from the larynx downwards. In extent and thickness it may vary from thin soft scattered patches to thick tough complete casts of the tubes, reaching to the finer bronchi.

Such membranes are composed of a network of coagulated fibrin containing bacteria and entangling leucocytes and red corpuscles. According to their thickness, so is the subjacent mucosa more or less involved in a necrotic process. Such false-membranes are frequently expectorated or expelled through the tracheotomy wound, usually as shreds

or ragged masses, though occasionally as more or less perfect tubes.

Fibrinous moulds of the bronchi may be found in the sputum of lobar pneumonia and of plastic bronchitis. Of the latter disease, these 'bronchial polypi' are pathognomonic, and though it is rare for more than very limited areas of the air-passages to be affected, yet perfect casts of the entire extent of these areas from the larger bronchi to the alveoli may be ejected. Expectoated as irregular, rolled-up and twisted masses, they may be shaken out in water into ramifying whitish or pinky-white moulds of the tubes, varying in length from one and a half to six or seven inches, and of a maximum diameter of half an inch, often with swollen ends corresponding to the infundibula. They are either hollow and membraniform or solid, and nearly always present indications of being made up of concentric layers. Sometimes only one of these casts may be expectoated, especially if a large one; at other times they may be re-formed again and again, and large quantities may be coughed up daily. Microscopically they consist of a fibrinous coagulum entangling epithelial cells, leucocytes, red corpuscles, fat-globules, and occasionally octahedral crystals. See BRONCHI, Diseases of.

In hæmoptysis small casts of bronchioles, consisting chiefly of coagulated blood, are sometimes found in the sputum.

Curschmann's Spirals.—In spasmodic asthma and also in pneumonia and bronchitis, spirally twisted bodies of a whitish colour may be seen in the sputum. They are said to be composed of a central slender core of a fibrinoid substance, enveloped in a layer of mucin. They are of variable length and breadth, are frequently covered with epithelial cells, and with colourless elongated octahedral crystals. See CHARCOT-LEYDEN CRYSTALS.

W. H. ALLCHIN.

R. G. HEBB.

CATALEPSY (κατάληψις, a seizure).—SYNON. : Fr. *Catalepsie*; Ger. *Starrsucht*.

DEFINITION.—A disease of the nervous system, characterised by attacks of powerlessness, commonly with loss of consciousness, and accompanied by a peculiar form of muscular rigidity, in which the limbs remain for a time in the position in which they are placed by passive movement. On account of the trance-like state which exists in the attack, the name is sometimes applied to simple trance, but should be restricted to the condition in which there is the peculiar state of the muscular system. The origin of the name is connected with the old spiritualistic pathology, which referred such sudden states to the action of an immaterial agency, and recognised as such only some immaterial agent of personal nature.

ÆTIOLOGY.—Catalepsy may occur at all ages between six and sixty years, and in both sexes, but it is incomparably more frequent in the female sex and in early adult life, at or soon after puberty. It is, in the majority of cases, associated with distinct evidence of hysteria. In other cases, in which no hysterical symptoms have preceded it, the affection may be traced to such exciting causes as give rise to the hysterical paroxysm. Nervous exhaustion is the common predisponent; and emotional disturbance, especially religious excitement, or sudden alarm, or blows on the head and back, are frequently immediate causes. It occasionally appears in the course

of mental affections, especially melancholia, and is said to occur as an early symptom of epilepsy, but it is much more likely that the fits thought to be epileptic were really hysteroid. In an imperfect form it has appeared to be due, in some cases, to paludal poisoning or to other toxæmic states, as chloroform-narcosis. In a few instances meningitis, and other organic cerebral or spinal diseases, have caused a cataleptoid condition; but these cases are too rare and diverse to allow of any inference from them.

SYMPTOMS.—Catalepsy is usually paroxysmal, attacks lasting hours or days being separated by periods of freedom; less commonly a single prolonged attack constitutes the whole affection. In some cases, headache, giddiness, or hiccough has preceded the attack. The onset of the special symptoms is usually sudden, commonly with loss of consciousness. The whole or part of the muscular system passes into a state of rigidity. The limbs remain in the position they occupied at the onset, as if petrified. The muscular rigidity is at first considerable, and movement is resisted; but after a short time the limbs can be moved, and then remain in the position in which they may be placed. The resistance to passive movement is peculiar; it is as if the limbs were made of wax, and hence the condition has been termed *flexibilitas cerea*. The rigidity commonly yields slowly to gravitation. The countenance is usually expressionless. The respiratory movements and heart's action are weakened. Substances placed in the back of the mouth are swallowed, but slowly. The state of sensibility varies; in profound conditions of catalepsy it is lost to touch, pain, and electricity, and no reflex movements can be induced even by touching the conjunctiva, a state of mental trance being associated. In other cases partial sensibility remains, and reflex phenomena may be excited. In rare instances hyperæsthesia is present. In induced catalepsy there is often a peculiar local exaltation of reflex action, so that stroking the skin over a superficial muscle causes an increased contraction of it. This involves a change of posture, in consequence of a definite sensory impression, and an analogous effect may be produced through the special senses, especially hearing; if a ticking watch be brought near the subject's ear, the posture is changed with a start, the head turned towards the object, and the eyes, if previously closed, may be opened, although the cataleptic condition continues as before. Consciousness, although usually lost, may remain, but it is seldom intact, being generally in an obscured condition. The temperature is commonly lowered in a long seizure. The attack may last a few minutes or several hours. Recovery is gradual or sudden; sometimes the patient at first is unable to speak. A sudden respiratory stimulus—such as blowing on the face—will often terminate an attack of induced catalepsy. Sometimes a strange periodicity may be observed in the occurrence of the paroxysms. In the intervals between the attacks, headache, giddiness, or hysterical manifestations may be present, or the patient may feel and seem perfectly well.

PATHOLOGY.—Concerning the nature of the disease there has been much speculation, but little definite knowledge. It may probably be placed between epilepsy and hysteria in the scale of maladies, but nearer the latter than the former, and as regards the nature of its chief feature, it may be regarded as essentially one of the motor manifesta-

tions. But there is also distinct interference with the intellectual processes, and interruption of the connection between the will and the motor centres.

To say this is only to express obvious facts in general terms, and affords no explanation of them. A careful consideration of their nature may give us at least the material for thought on the subject. The wax-like rigidity is an excess of the action by which muscles are constantly adapted to posture, i.e. to the distance between their attachments, and yet preserve the same degree of physiological tone. This is effected by a reflex process, the afferent impulse for which probably comes from the afferent muscle-nerves, and is generated by the sum of the related tension and compression of the interstitial tissue in which these nerves begin. The motor cells (and therefore the muscular fibres) are active in inverse proportion to these impulses, and as the opponents of a passive movement relax, the muscles shorten that correspond to it in their action; they are thus adapted to posture, and, if this process is in excess, the cataleptic rigidity must of necessity ensue. But it is probable, on many grounds, that the afferent impulses from the muscles have a double action—a lower on the motor centres of the spinal cord, and a higher through the cerebellum, on the motor centres of the cortex cerebri. The phenomena suggest that the action is similar on each; since the cortical cells govern the spinal cells, their functional states must be in related correspondence. Thus the afferent impulses that regulate adaptation to posture must do this through both cortical and spinal centres simultaneously. The excessive action of catalepsy may be in the cortical and not in the spinal mechanism. This would enable us to understand the otherwise strange fact, that the cataleptic state may be induced by influences acting on the brain, as in the induced catalepsy of hysteria. The motor cortical centres, whence the pyramidal fibres proceed, are probably the lowest of the centres of the cortex; the induction of catalepsy may consist simply in the inhibition of higher centres that act on and through them and normally restrain them. The over-action of these entails the over-action of the spinal centres, and the wax-like rigidity results. Thus, too, we can understand that consciousness should be lost or strangely changed during the attack, and its relation to emotion as a cause. So, too, it is clear that every forced change of posture will leave the condition of the centres essentially unchanged, although there will be a slightly different distribution of activity. Arrest the inhibition which prevents the higher cortical centre from acting on the lower, and the resumed control involves restraint of the over-action of the latter and of the spinal centre, and the cataleptic state is at an end.

DIAGNOSIS.—The peculiar rigidity of catalepsy is characteristic, invariable, and renders the diagnosis a simple matter. Hysteria with tonic spasm has been erroneously termed catalepsy, but is distinguished by the local position of the spasm, and the fact that it does not yield to passive force. The malady most likely to be confounded with catalepsy is tetany, since in it there are attacks of tonic spasm involving all the limbs. But in this the rigidity is fixed; it cannot be overcome, and the posture of the limbs changed; while the hands are in a characteristic posture, with the fingers straightened at the middle joints, and their points and that of the thumb brought together. The condition is some-

times simulated: in true catalepsy the rigid limb slowly yields to the influence of gravitation, and more rapidly if a weight be attached to it; in the feigned form the limb and weight are held firm.

PROGNOSIS.—The prognosis is favourable in simple catalepsy in proportion to the freedom of the intervals from affections of sensibility or motion. In pronounced hysteria and psychical affections the condition is often obstinate; and, by interfering with the due nourishment of the system, may cause grave inanition.

TREATMENT.—During the attack itself little can be done save an attempt, which may be repeated at intervals, to rouse consciousness by external stimulation. The ordinary applications—ammonia to the nostrils, cold douches, &c.—often fail in the spontaneous form, but this does not hold true of most cases of induced catalepsy, in which any stimulus that excites a respiratory effort commonly arouses the patient and cuts short the attack. A pinch of snuff will, however, often succeed in both varieties. Another effectual stimulant is faradisation. It may be applied to a limb or to the cervical spine. The current should be gentle at first, and gradually increased. Emetics are also useful in arresting an attack.

The writer has found subcutaneous injection of apomorphine, $\frac{1}{10}$ to $\frac{1}{2}$ of a grain, an efficient remedy for similar paroxysmal conditions; with the onset of nausea, about five minutes after the injection, consciousness is regained, and all spasm ceases. In the intervals between the attacks the treatment is that of hysteria. Iron, antispasmodics, especially valerian, aloetic aperients, and cold baths, are the most effectual measures. Firm moral treatment is also indispensable. Removal from home-influences is often necessary to effect a cure.

CATAMENIA, Disorders of.—See MENSTRUATION, Disorders of.

CATAPLASM (κατά, down; and πλάσσω, I mould or smear).—A synonym for a poultice. See POULTICE.

CATARACT (*cataracta*, an obstacle).—SYNON.: Fr. *Cataracte*; Ger. *Staar*.

DEFINITION.—Cataract is an opacity, partial or complete, of the substance of the crystalline lens or of its capsule. The former is called *lenticular*, the latter *capsular*. Either may exist separately, or the two may occur together (*capsulo-lenticular*). From a surgical point of view it is sometimes necessary to embrace within the definition of cataract some extra-capsular opacities, such as inflammatory deposits or the remains of embryonic structures within the pupillary area of the anterior or of the posterior layer of the capsule. Such opacities are called *false* cataracts.

ANATOMY AND PHYSIOLOGY.—The lens consists of three parts: first, the substance of the lens, which is made up of fine, flattened fibres; second, a layer of endothelium lining the anterior part of the capsule; and, third, the capsule, which surrounds and encloses the lens-substance and the endothelium. The fibrous portion of the lens consists of a harder central part, or *nucleus*, and a softer external portion, or *cortex*. The cortex is disposed around the nucleus in thin concentric layers, each of which is subdivided into sectors, separated by fine radiating

fissures, which make up the rays of the stella existing at the anterior as well as at the posterior surface of the lens. The lens-fibres and the endothelium are descended from the external layer of the blastoderm—the epiblast. The capsule of the lens seems to have a double origin, the inner layer being derived from the lens-substance, while the outer is the offspring of mesoblastic elements. The growth of the lens continues throughout life. It is effected by the apposition upon the nucleus of lens-fibres derived from the endothelial cells lining the anterior capsule.

The crystalline lens, being a non-vascular body, is nourished by imbibition from surrounding fluids. It is probable that these fluids are modified by their passage through the vitreous humour and through the capsule; for if the anterior or the posterior capsule be ruptured, the lens becomes opaque. In health, the nutritive fluids pass from the periphery to the centre through the stellate clefts and other channels which exist throughout the lens. Waste-products are apparently driven inwards to the centre, to undergo elimination in a manner not yet fully understood.

After middle life the fibres of the lens gradually assume a yellowish or brownish tint, and the rate of formation of new fibres diminishes. As age advances they become drier, harder, and less elastic, and the capsule thickens. If a senile lens be ophthalmoscopically examined with a strong magnifying-glass, semi-translucent lines, flaws, spaces, and vacuoles, and fine dusty films, may often be discovered, even when there are no coarse physical opacities. These phenomena are due to shrinking of the lens-fibres and loosening of the lamellæ from one another, with accumulation of fluid and lens-debris in the spaces thus formed. Still later, separation of the cortex may take place, both from the nucleus and from the capsule.

PATHOLOGY.—Any fault in the original constitution or development of the lens, or any alteration in its nutrition at any subsequent period, will, sooner or later, induce opacity of some portion of the lens or of its capsule.

The chief *embryonic* abnormalities are (1) inherent faults of the epiblastic cells which constitute the rudimentary lens. The fibro-cellular portions of the lens either do not become transparent, or, if they do clear, their vitality is low, and they soon degenerate. The whole lens is either opaque from the beginning (*congenital cataract*), or becomes opaque within a few months or years (*infantile* or *juvenile cataract*). (2) A temporary or permanent disturbance may occur during intra-uterine life to thwart the development of a lens. If the interference be violent its effects may be permanent, so that the whole of the lens becomes opaque; but if the check be of a temporary character, only a thin layer of opacity may be produced. The nucleus of the lens, though not unaltered, is usually translucent and the cortex transparent; but the intermediate layers—that is, the sub-cortical or perinuclear—are more or less opaque. This form of opacity is called *lamellar cataract*, because in sagittal section it is seen to be disposed in layers around the nucleus; or *zonular cataract*, because the opaque portions, when looked at *en face*, are bordered by a transparent zone of clear cortex. It would seem that the layers which are opaque are either those which were immediately sub-capsular at the time when the disturbance took place, or those which were produced by the endothelial cells during the period

of disturbance. In some rare cases there are two or more concentric layers of opacity, with intervening layers of clear substance, as if there had been several disturbances at different epochs, followed by intervals of normal growth. Lamellar cataracts may be found in eyes otherwise healthy, but they are sometimes associated with developmental defects of the eye and of the general organism, an almost invariable concomitant being deficiency of enamel of the permanent teeth, especially the first molars, the incisors, and the canines (Hutchinson), and not infrequently there is a clinical history of 'fits,' or other evidences of a neurosis. (3) As the result of inflammation of the cornea, uveal tract, or vitreous humour during intra-uterine life, single or multiple opacities may form in the capsule and sub-capsular layer. These are called *congenital capsular cataracts*, and are most common at the anterior pole. They may, however, be scattered about the anterior surface, or lie about the posterior pole of the lens. These opacities consist of proliferation of the endothelium and granular disintegration of the superficial cortical layers, similar to those changes which produce capsular and sub-capsular opacities after birth. It is, however, not improbable that congenital anterior polar cataracts may sometimes be due, not to inflammation, but to retarded separation of the involuted lens-vesicle from the cornea, and delayed closure of the vesicle. This retardation may permit of the intrusion of mesoblastic elements within the vesicle, and these would still further increase the opacity about the capsule. This may conceivably cause an axial opacity, the so-called *spindle-shaped cataract*. (4) *Congenital false cataracts* may be due to the presence of extra-capsular opacities upon the anterior or the posterior pupillary areas. These opacities may be the results of inflammatory exudations, but more commonly they are due to an arrest of development in its final stage, and more particularly to the defective removal of the embryonic vascular capsule of the lens. This state of incompleteness may be designated by the Aristotelian term *Ateleia*.

The alterations in nutrition which, *after birth*, lead to the formation of cataract may be classified as follows:—

(1) *Diminution in the quantity* of the nutrient elements, without material alteration in their quality. This diminution may be due to many causes: (a) mechanical obstacles impeding due access of the fluids; (b) damage to the secretory apparatus consequent upon chronic atrophy of the ciliary body and choroid; (c) general malnutrition, anæmia, cardiac, renal, or other visceral disease; or (d) simple old age.

Mere diminution of the quantity of nutritive elements operates slowly on the nutrition of the lens, and the opacity which results first manifests itself in or about the nucleus—that is to say, the parts most remote from the sources of the nutrient fluids.

(2) *Alterations in the quality* of the nutrient elements. These may be due to: (a) congestion, inflammation, or any other morbid state of the secretory organs of the nutritive fluids—namely, the ciliary body, iris, choroid, and retina; (b) changes in the vitreous or in the aqueous humour; (c) morbid states of the blood and tissues, as in gout, glycosuria, albuminuria, &c.; (d) changes in the physical, chemical, or vital properties of the capsule or of its endothelium, in consequence of which the

fluids that pass through the capsule are not properly prepared for the due nutrition of the lens; or (*e*) impeded elimination of waste-products, whether from the lens itself or from the whole eyeball.

Alterations in the quality of the nutrient elements act more or less speedily, and if the alteration be very great, as in rupture of the capsule, they are very prompt in producing opacities. These affect primarily the sub-capsular and the cortical layers, with which the altered fluids first come into contact. If the alteration be intense, but of brief duration, as in the case of perforating ulcer of the cornea in purulent ophthalmia of children, the change may be limited to a circumscribed area of the capsule and sub-capsular layers, giving rise to an *anterior polar* cataract, or, if this opacity assume a conical shape, *anterior pyramidal* cataract. In alterations of less intensity, but of continuous duration, due to chronic morbid states in the posterior segment of the globe, such as retinitis pigmentosa, slowly forming opacities may occur in the posterior sub-capsular layers of the lens, beginning at the pole of the lens, and extending thence in a radial direction along the rays of the posterior stella, giving rise to *posterior polar* or *stellar* cataracts.

(3) *Alterations of quantity and quality combined.* This co-operation obtains in most of the cases of cataract; and the effects of the two conditions are variously combined. The great majority of cataracts are cortical, because there are comparatively few cases, even in apparently healthy eyes, where there does not exist some difference in the quality of the nutrient elements, as well as falling off in quantity.

MORBID ANATOMY.—In senile cataracts, and in most slowly forming cataracts, the opacity of the lens-fibres is merely an extension of physiological senile changes, and is usually preceded by the formation of spaces and vacuoles between the fibres and the lamellæ due to shrinkage and sclerosis, as already described. Priestley Smith's investigations have shown that a diminished rate of growth of the lens precedes cataract. According to Otto Becker the initial cause of senile cataract is drying of the nucleus and its separation from the cortex, the gap between them being filled by a fluid which is probably derived from the fibres. In more rapidly forming cortical cataracts it may often be observed that the opacity begins in the sub-capsular layers and about the borders of the rays of the anterior stella. Instead of shrinkage and sclerosis, the fibres may swell and become softer. In some cases the rays of the stella are broadened, but whether they are or not, a hazy line may often be traced along one or both of the edges of the ray, in the ends of the cortical fibres. From the ends of the fibres the opacity extends along their lengths towards the equator, until the whole of the cortex is implicated. The endothelium also undergoes changes, giving rise to triangular patches of glistening opacities which may present a mother-of-pearl appearance. When once the opacifying process begins in any part of the lens, it tends to progress till the whole is involved. The cataract is then said to be *ripe* or *mature*.

If a ripe cataract be allowed to remain within the eye indefinitely, it may undergo further degenerative changes and become what is called *over-ripe*. In some instances the lens-substance shrinks and becomes hard and calcareous, and the capsule thickens and grows more opaque. In other cases

the cortex liquefies, allowing the harder nucleus to move within it (*Morgagnian* cataract). Over-ripe cataracts may also become loosened, in consequence of softening or rupture of the suspensory ligament. Fluidity of the surrounding vitreous humour may likewise occur, and then on slight provocation the loosened lens may fall into the vitreous.

A peculiar form of degeneration sometimes occurs in the lens, producing what is called *black* cataract. This is commonly thought to be due to the staining of the lens by blood-pigments, and in some cases this may be so; but, according to a careful spectroscopic examination by MacMunn, no blood-pigments were found, but the lens was infiltrated with a pigment analogous to melanin.

ÆTIOLOGY.—Besides the causes and conditions already described, there are other circumstances which may induce cataract, or at least predispose to it. The most important of these are as follows:—

Age.—Cataracts occur more frequently in infancy and in old age than in early adult and middle life, except when due to disease of the eye or to injuries.

Sex.—The two sexes are about equally affected, except in respect of traumatic cataract, in which males greatly preponderate. *Heredity.*—Hereditary influences may determine the occurrence of cataract in several ways. There may be the inheritance of actual (congenital) cataract or of a disposition to cataract. In either case the descent seems to pass more through the male than the female line. *Occupation.*—Certain occupations predispose to cataract, especially such as necessitate close application of the eyes to near work, or involve stooping positions or exposure to bright light, more particularly if light be combined with heat (as in the occupation of smiths, cooks, stokers, &c.), and occupations in which the eyes are exposed to irritating fumes and vapours. Uncorrected *errors of refraction* and accommodation may favour the production of cataract by overstraining the accommodation, and by the frequent and successive changes which the capsule has to undergo. These strains not only increase the wear and tear of the lens, but facilitate the loosening of the cortex of the lens from the capsule. Hypermetropia and astigmatism may predispose to cataract in another way. The incessant strain upon the ciliary muscle required to correct hypermetropia involves constant congestion of the ciliary body and the base of the iris. The nutritive fluids secreted during this state are not perfectly normal; they are in some measure altered in quality and will therefore sooner or later make their influence felt on the transparency of the lens.

Injuries.—Wounds of the capsule are generally soon followed by opacity, which occurs more quickly in proportion to the size of the rent and the youth of the patient. Perforating wounds of the cornea, especially when followed by suppuration, may induce cataract even though the capsule have not been perforated. Blows on the head, face, or brow, shocks and jars of the body, may also be followed by cataract, either from causing flaws or cracks or rents in the capsule or by rupture of the suspensory ligament. Other conditions which accompany and apparently predispose to cataract are degenerative changes in the blood-vessels, especially of those of the head and neck and of the eye; diseases of the orbit, or changes in the orbital vessels; cardiac disease, renal disease, gout, and diabetes. It is probable, however, that the influence of diabetes in the production of cataract has been overrated. The

number of diabetic persons who get cataract is comparatively small, and when cataract co-exists with glycosuria there is no necessary causal relationship between the two. It has been stated that ergotism often leads to cataract (J. Meyer).

CLASSIFICATION.—Cataracts have been classified in many ways, as (1) according to *age*—congenital, juvenile, senile; (2) to *stage*—incipient, progressive, stationary, immature, mature; (3) *consistency*—fluid, soft, hard, and mixed.

Following the indications afforded by the consideration of the pathology and causation of lenticular opacities, cataracts may be arranged into five main groups according (1) as they are due to developmental abnormalities—*embryonic*; (2) as they occur independently of obvious disease of the eye—*idiopathic*; (3) as they are associated with obvious disease of the eye—*sympathetic*; (4) as they follow wounds or injuries of the eye—*traumatic*; and lastly (5) as they are due to the opacification of lens-matter remaining within or on the capsule at the time of operation for the removal of cataract, or of lens-matter which may have grown subsequently and then become opaque—*deutero-pathic* or subsequent (*δευτεροπαθές*, I suffer later). Within one or other of these groups all the varieties of cataract may be arranged according as they implicate (1) the nucleus; (2) the perinuclear region (lamellar); (3) the axis (spindle-shaped); (4) the cortex, anterior or posterior; (5) the equator; (6) the capsule, anterior or posterior; (7) the external surface of the capsule—extra-capsular—which may be congenital or acquired.

SYMPTOMS.—The chief subjective symptom of senile and other acquired cataracts is impairment and 'fogginess' of sight, especially for distant objects. As the cataract advances, this dimness increases, until the appreciation of form and colour may be lost; but, in eyes otherwise healthy, the power of discerning light always remains, even though the lens be quite opaque. In ordinary daylight the eye may still be able to 'count fingers' at a distance of six to twelve inches, or see the movement of a hand at a distance of twelve to eighteen inches (hand-movement); and in a darkened room the eye should be able not only to see a lighted candle at a distance of ten to fifteen feet, but should be able also quickly to indicate its position in various parts of the field of vision without movement of the eyes or head. This would indicate that there is a good *perception* of light, good *projection*, and a good *field of vision*. In the early stages of cataract, especially when the opacity occupies the pupillary area, patients may see better when the eyes are shaded, the pupil being thereby made to dilate; a bright light embarrasses and distresses them. *Muscae volitantes* are also often seen; these may be due to congestion of the ciliary blood and choroid which may have preceded cataract, or they may be the results of the straining efforts to see through a hazy lens. Another common symptom is the multiplying or splitting of objects, especially of lights (*monophthalmic polyopia*). The amount of impairment of sight is not always in proportion to the amount of appreciable opacity; diffused haziness about the nucleus or about the pupillary area is more hampering than well-defined striæ or sectors with clear interspaces. There may be dense opacities at the equator with perfect acuteness of vision. An occasional early symptom of cataract is a change in the refraction of the eye,

leading to what some persons describe as getting 'the second sight.' Eyes that have required strong convex glasses for near work prefer weaker ones, or none at all; and those who have needed convex glasses for distance may find that they see better without them, or even with concave glasses. Many children with zonular cataract are thought to be merely short-sighted, and often they are short-sighted, but the true cause of the defect is frequently not discovered till the 'optician' has failed to get good vision by means of spectacles.

DIAGNOSIS.—In all cases of failing sight, whether opacities are to be seen or not by means of direct light or by so-called focal or oblique illumination, the media of the eye should be examined with the ophthalmoscope. Owing to thickening of the lens-capsule, the pupils of old persons are sometimes grey instead of black, and the lenses may seem to be opaque when they are not really so; and in glaucomatous eyes the change of colour which takes place in the cornea and in the lens not infrequently suggests cataract even when the media are translucent. Diagnosis of advanced cataract is easy, but in slighter cases careful examination of all parts of the lens may be needed. The aims of diagnosis are to recognise the presence of the cataract, to ascertain its seat, extent, consistence, and its relations or complications, and to discriminate it from other morbid states which may be mistaken for it. Examination of the anterior part of the lens, the capsule, anterior cortex, and the nucleus may be made with 'focal illumination,' i.e. by concentrating light upon the eye by means of a magnifying-glass. The equator of the lens and the posterior cortex require the ophthalmoscope for their examination.

Anterior extra-capsular opacities, whether inflammatory deposits or remains of the capsulo-pupillary membrane, project beyond the level of the capsule. The latter have usually attachments to the anterior surface of the iris (*circulus minor*), whereby they are distinguished from inflammatory adhesions (posterior synechiæ) which are connected with the edge and posterior surface of the iris. Capsular cataracts may be single or multiple. Anterior polar cataract occurs as a small circumscribed dot in and behind the centre of the capsule; when viewed in profile the dot can be seen to project slightly beyond the general level of the capsule; occasionally it projects considerably and is conical (pyramidal cataract). Both these cataracts are generally associated with nebula or leucoma of the cornea. Multiple capsular opacities may be scattered irregularly or arrayed in a circle. Cortical opacities assume many shapes—striæ, wedges, or irregular patches. When the opacities are in the anterior cortex, they are convex in their arrangement; when in the posterior they are concave. Equatorial opacities may be partial or complete, continuous or interrupted, limited as a corona to the periphery, or send tapering offshoots towards the anterior and posterior cortices. Perinuclear opacities may be circumscribed or diffused. The circumscribed (lamellar or zonular cataracts) are best seen with the ophthalmoscope when the pupil has been dilated by a weak solution of atropine or other mydriatic. Lamellar cataract appears as a greyish disk surrounded by a clear zone. If the nucleus be translucent the disk is most opaque at its edge; but if the nucleus be itself opaque, then the opacity is densest in the centre. The edge of the disk may be sharply

defined, or indented or broken by centrifugal striæ. Nuclear opacities may be dense and diffuse, as in some congenital cataracts, or they may appear as a brownish or yellowish undefined blur or cloud, as in early senile cataract. Posterior polar cataract can be properly seen only with the ophthalmoscope. It may assume the form of a smaller or larger dot, or of several dots, or of radiating streaks. The position of the opacity is determined partly by its remoteness from the pupil, and partly by the small excursions it makes in the various movements of the eye, the posterior pole of the lens being immediately in front of the centre of rotation of the globe.

Whenever practicable, it is desirable in all forms of cataract to examine the state of the optic nerve and fundus of the eye. The data thereby obtained may influence the prognosis and the later treatment. When the cataract is mature the pupil is uniformly white or greyish, and the opacity comes up to and seems to touch the pupillary edge of the iris, and no reflex can be obtained by means of the ophthalmoscope. If the cortical layers are not opaque, a shadow of the iris can be thrown into the lens by means of oblique illumination, giving the appearance of a gap between the opacity and the edge of the iris. For surgical purposes it is not necessary that the whole of the lens-substance should be opaque; it is enough that the cortical layers be opaque, for then the connection between the cortex and the capsule is broken, and the endothelial cells have lost their power of growing fresh lens-fibres. It is not always possible to estimate the consistency of a cataract; but, as a rule, cataracts which begin in the cortex, or occur in persons under the age of thirty years, or are rapidly formed, are usually 'soft'; such cataracts are generally whiter and more opaque than harder ones, and the opacity is often patchy or diffused.

The failing sight of chronic glaucoma is sometimes ascribed to cataract. By the ophthalmoscope and by palpation, the error may easily be avoided. When the lens is not opaque in glaucoma the diagnosis is simple, mere absence of opacity excluding cataract; but when, in glaucoma, the lens is also opaque, the diagnosis may present some difficulty. In chronic glaucoma the characteristic symptom is increased hardness of the eyeball. Usually a history of haloes seen round artificial light may be elicited, with perhaps attacks of neuralgia and redness of the eye. The pupils are semi-dilated and very sluggish, if not immobile, and the anterior chamber is shallow, and the sight is more impaired than the cataract accounts for. In advanced (absolute) glaucoma there is an entire abolition of the perception of light.

PROGNOSIS.—Cataract may be considered, as regards its prognosis, from two points of view: first, when it is immature, as to its probable course; and, secondly, when it is mature, as to the prospects of recovery of sight after operation. Some cataracts may remain stationary throughout a long life: such are anterior polar, anterior pyramidal, and zonular cataracts. Others progress slowly, such as posterior polar cataracts. Cortical cataracts, as a rule, advance more rapidly than nuclear ones, and soft cataracts more rapidly than hard. Generally the progress is quicker the earlier the cataract occurs, and the closer its association with morbid states of the eye or with injury. When cataracts are sharply defined, confined to the

equator of the lens, or present only a haze or blur in or about the nucleus, or when the cortical striæ are few and fine and well-defined, with clear interspaces, and the eyes are otherwise healthy, and the sight good, the progress will usually be slow; but when the opacities are dense, irregular, ill-defined, diffuse, especially where they extend far along the anterior or posterior cortical layers, with rapidly failing sight, or with sight bad out of all proportion to the amount of actual opacity, or when there is obvious irritative or inflammatory disease of the eye, or when there is grave visceral or other constitutional disease, such as gout, diabetes, nephritis, then the progress will probably be rapid. But it should be remembered that cataracts which may have been very slowly progressing may at any time take a sudden and rapid start and progress quickly. The usual course, in senile cataract, is from one to four years or more.

As regards *mature* cataract, the prognosis in reference to operation is good in proportion as the eye is otherwise sound, and the general health good. Where there is a history of attacks of pain or of redness in the eye, or where there are signs of past disease, whether iritis or choroiditis or retinitis, or where there is a high degree of myopia, or where the iris is discoloured and lustreless, and sluggish or immobile, or where it is tremulous, or where the anterior chamber is much deeper than natural or much shallower, or where there is a chronic conjunctivitis, ciliary blepharitis, or catarrh of the lacrimal sac, or where the tension of the eye is too high or too low, the prognosis is more or less unfavourable. Nystagmus, squint—especially divergent squint—are unfavourable concomitants; and the prognosis is, of course, less favourable when it is known that there was antecedent disease of the fundus, or when, failing this knowledge, the perception of light is poor, and the projection bad, and the field of vision contracted or irregular. Where there is no perception of light, the prognosis is hopeless.

TREATMENT.—From a medical point of view the treatment of cataract is rather preventive and palliative than operative.

Preventive.—Little can be done, directly, to prevent many of the embryonic forms of cataract, and those other cataracts which are due to simple diminution of the *quantity* of nutrition, of which pure senile cataract is the type. On the other hand, it is at least ideally possible to prevent the occurrence of many of those cataracts which are due to alterations of *quality* of nutrition. By the prevention or the avoidance of those general and local morbid conditions which induce these qualitative alterations, or by their early and effectual treatment, *secundum artem*, by obedience to the laws of personal and public hygiene, by conforming to the requirements of healthy sight, by the scientific correction of errors of refraction and accommodation, by adequate protection of the eyes during those occupations which entail risks of physical, thermal, or chemical injuries, cataract may often be prevented, or its progress arrested, if perchance initial changes have already begun.

Palliative.—If opacity of the lens exists, but not to an amount sufficient to materially impair sight, it is sometimes possible, by general and local measures, to improve the special nutrition of the lens, and thereby to retard the progress of the cataract. In some cases, where slight endothelial and cortical

opacities occur during transitory inflammation of the cornea, iris, or choroid, or during exacerbations of diabetes and other diathetic diseases, the opacities may gradually disappear on the resumption of normal nutrition after the subsidence of the inflammation or the amelioration of the general health. But, except within these narrow limits, genuine cataractous opacities are incurable and irremovable by any means known to positive science other than operation.

Nevertheless the inconveniences which attend progressing cataract may be palliated by alleviating local irritation, by the use of tinted glasses, by shading the eyes from bright light, by correction of optical errors, or by the use of stenopæic glasses. When the opacity, whether congenital or acquired, is limited to the pupillary area of the lens, vision may be improved by moderate dilatation of the pupil, by means of weak solutions of atropine (gr. $\frac{50}{1000}$ to gr. $\frac{1}{10}$ in an ounce of water), or other mydriatic. In any case, if the eyes be otherwise healthy, moderate use of the eyes may be indulged in, short of discomfort and fatigue.

Operative.—The operative procedures for the removal of cataract are: First, *discission*, or *keratonyxis* (κέρας, horn [cornea]; ρύσσω, I prick), in which the anterior capsule is torn by a fine needle passed through the cornea. The lens-substance, being thereby exposed to the disintegrating action of the aqueous humour, gradually liquefies and is ultimately eliminated by the absorbent vessels. Secondly, *discission with evacuation*. The capsule is torn as in discission, but the lens is more freely broken up. The fragments are then, or within a few days, removed by a grooved curette through a narrow incision immediately within the corneal margin (linear extraction), or withdrawn by aspiration through a fine tube (suction). The third operation is *extraction*, in which an incision is made at or near the corneal margin, the capsule divided and the lens extruded by gentle pressure. Until quite recently a portion of the iris was in the modern operation removed (iridectomy) at the time of the extraction-operation, or a few weeks or months previously (preliminary iridectomy). But some surgeons now try to dispense with the iridectomy, or only do it when the cataract cannot otherwise be safely and efficiently removed. Discission with or without evacuation is applicable to 'soft' cataracts, while extraction is usually reserved for 'hard' cataracts. Soft cataracts may be operated on almost at any time and in any stage; but hard cataracts are, as a rule, not extracted until they are 'mature,' though there are many circumstances which may suggest and justify departure from this rule. An immature cataract may be operated on whenever both eyes are so affected that the patient is unable to read ordinary print or to follow his occupation or profession.

It may here be remarked that when zonular cataract is slight, and does not cause appreciable impairment of sight, operation may be indefinitely deferred. If, on the other hand, the opacity is more pronounced, and the degree of impairment of vision is such that education or occupation cannot be comfortably pursued, operative interference is called for. The precise procedure will depend upon circumstances.

When the eye has recovered from the effects of the operation, spectacle-lenses are needed to correct the error of refraction due to the absence of the

crystalline lens (*aphakia chirurgica*). Except in very short-sighted eyes convex lenses are required. The strength of the lens will depend upon the refraction of the eye, but ordinarily for distance a lens of about 10 dioptries (4-inch) is needed, and for near work about 14D. ($2\frac{3}{4}$ -inch). If astigmatism (see VISION, Defects of) be present, then cylindrical lenses must be added to the spherical. In any case, it is desirable that an eye which has been operated on should not be used too soon, nor, at first, for too long a time.

Sometimes it happens after the removal of a cataract that, owing to the presence of hazy or opaque lens-capsule within the pupil, it is not possible to obtain useful vision by the most accurate optical correction. It will then be necessary to tear through the membrane with one or two fine needles (*needling*), and thereby effect a clear opening opposite the pupil.

JOHN TWEEDY.

CATARRH (κατά, down; and ῥέω, I flow). SYNON.: *Coryza*; Fr. *Catarrhe*; *Coryza*; Ger. *Katarrh*; *Schnupfen*.

The term catarrh is applied to inflammation or congestion of any of the mucous membranes, attended with increased secretion. The term is, however, often limited to an inflammatory affection of the upper part of the air-passages. See NOSE, Diseases of.

CATARRHAL (κατά, down; and ῥέω, I flow).—Pertaining to catarrh, both in its pathological and clinical significations—for example, catarrhal products, catarrhal pneumonia, catarrhal attack.

CATHARTICS (καθαίρω, I cleanse).—This word is sometimes used as a synonym for purgatives; but in a more limited signification it means purgatives of moderate activity. See PURGATIVES.

CAUDATE NUCLEUS.—See CORPUS STRIATUM.

CAUSTICS (καίω, I burn).—DEFINITION. Substances or measures which destroy organic tissues with which they may be brought in contact.

ENUMERATION.—The caustic substances in most common use are Potash, Soda, and Lime; Nitric, Hydrochloric, Sulphuric, Chromic, Lactic, and Glacial Acetic Acids; Red Oxide, Acid Nitrate, and Perchloride of Mercury; Carbolic Acid; Chloride of Zinc; Chloride of Antimony; and Arsenic. The ordinary caustic measures are the galvano-cautery; Paquelin's cautery; the red-hot iron; and moxæ. See also POISONS.

USES.—Caustics are chiefly employed to destroy unhealthy, exuberant, or malignant growths; to establish issues for the purpose of counter-irritation (see COUNTER-IRRITATION); and to destroy poisons when introduced into the body by breach of the external surface.

T. LAUDER BRUNTON.

CAUTERETS, in the French Pyrenees.—Sulphur-waters. See MINERAL WATERS.

CAVERNOUS.—A peculiar quality of sounds heard on auscultation of the lungs, indicative of the presence of a cavity. See PHYSICAL EXAMINATION.

The term is also used to denote a special kind of tissue consisting of fibrous trabeculae arranged to form intercommunicating spaces, found in the penis

and in some varieties of new-growth. See TUMOURS; ANGIOMA.

CAVITY, Pulmonary.—SYNON.: *Vomica*; Fr. *Vomique*; Ger. *Lungengeschwür*.

DEFINITION.—A cavity is a hollow space in the substance of the lung, formed by destruction of pulmonary tissue. Spaces due to dilatation of normally existing channels, such as the bronchi, are not properly called cavities unless the surrounding substance of the lung is invaded and forms part of the wall. The term is sometimes unnecessarily restricted to such cavities only as communicate with a bronchus.

ÆTIOLOGY.—(1) The great majority of pulmonary cavities are due to the softening of tubercular foci; it is therefore to tubercular cavities that reference will here be principally made; (2) the next most frequent cause of excavation of the lung is ulceration extending through the wall of a dilated bronchial tube (bronchiectasis); other causes are (3) the action of rarer forms of micro-organisms, such as actinomyces or aspergillus; (4) abscess of the lung, due either to acute lobar or lobular pneumonia, to extension from the pleural or abdominal cavities, to pyæmia, or to inhaled foreign bodies (coins, tracheotomy tubes); (5) gangrene of the lung; (6) ulceration of new-growths; (7) hydatid cysts, the contents of which have been evacuated, may form spaces closely resembling true cavities.

MODE OF FORMATION.—(1) *Tubercular cavities.* The deposit of tubercle-bacilli in the lung is followed by the formation of the small inflammatory nodules known as tubercles or grey granulations. Around these is a zone of inflammatory consolidation of the lung. As the process spreads, masses of these tubercles coalesce and considerable areas of consolidation may result. At the periphery of these areas much inflammatory fibrous tissue is frequently formed. Partly owing to the cutting-off of the blood-supply to the central portions of the consolidated mass by the contraction of this fibrous tissue, and partly by the direct action of the toxins of the tubercle-bacillus, necrosis of the central portions of the solid area is brought about. The process is then known as caseation (see CASEATION). In course of time the destructive process invades the wall of a bronchial tube, which gives way and permits the entry of the caseous material into the air-passages. This is then coughed up, and the space in which it originally lay remains empty, constituting a cavity.

(2) In the condition known as bronchiectasis dilatation of the bronchi in some portion of the lung occurs, and stagnation of the contents of these tubes takes place (see BRONCHI, Diseases of: 4. BRONCHIECTASIS). Decomposition of the retained secretion ensues; the walls of the bronchus are irritated by the products of putrefaction, and ulceration is the result. The process extends into the surrounding lung-tissue, which is generally already the seat of chronic interstitial fibrosis, and thus irregular excavations are formed: The relation of such cavities to the original bronchus is often difficult to trace: the fact that an inflamed and expanded bronchial tube enters and leaves the cavity, and that traces of bronchial tissue may be found in its wall, together with the existence of dilatation of bronchi in surrounding parts, may throw light on the nature of the process.

VARIETIES OF CAVITY.—According to the acuteness or chronicity of the disease from which the

excavation results, and the subsequent changes which may take place, cavities present very different characters. In the most acute cases of tuberculosis, as in instances of abscess or gangrene of the lung, the cavity consists of an irregular space, with softened ragged walls, lying in the midst of consolidated or partly consolidated lung-tissue. If gangrene has occurred the walls may be black, sloughy, and very fetid: in any case they will be soft and friable, with shreds of necrotic tissue adherent to their surfaces. In less acute cases, constituting the majority of tubercular cavities, the walls are less soft and ragged, consisting to a great extent of fibrous tissue, the result of chronic inflammation of interlobular septa; to their surfaces masses of caseous material may be seen here and there adherent. In still more chronic cases the walls may wholly consist of fibrous tissue, lined by a thin layer of granulations. The walls are then smooth and firm, and the cavity will tend to have a more distinctly rounded shape, owing to obliteration of irregular outgrowths by contraction of the fibrous capsule. This appearance is presented by old cavities in which the actual process of destruction has ceased and the disease become quiescent. The process may, however, at any time again become active and ulceration take place in the walls, so that mixed forms of cavity result, in which the walls are smooth and resistant in some places, and ragged and ulcerated in others.

CONTENTS.—Since an active cavity is practically an abscess, the contents of such consist largely of pus—that is, of leucocytes and albuminous fluid. In tubercular cases this will be mixed with caseous material which may contain elastic fibres from the broken-down lung-tissue. The walls, even of quiescent cavities, often continue to secrete purulent material, so that expectoration may continue after active disease has ceased. In bronchiectatic cavities and in some tubercular vomicæ the contents are very offensive owing to putrefaction, and cause the breath of the patient to be intolerably fetid. Rarely in old cavities organisms from the air may effect a lodgment, and moulds, such as aspergillus, may grow on the walls and appear in the expectoration. In cases due to actinomycosis small yellowish masses of the ray-fungus may be found in the pus.

BLOOD-VESSELS IN CAVITIES.—In the process of excavation blood-vessels, being more resistant than the other tissues, may remain for long periods intact. Thus bands consisting of blood-vessels, with a certain amount of fibrous tissue, may frequently be seen crossing tubercular cavities. In course of time the walls of such vessels are invaded by the inflammation, and thrombosis with obliteration of the lumen generally results. In some cases, however, the wall of the vessel is weakened without the occurrence of thrombosis; dilatation results and an aneurysm is formed. This will tend to fill the cavity while the latter is small, and to increase gradually along with it. Sooner or later a point is reached when no further expansion of the vessel wall can take place, and rupture of the aneurysm occurs, leading to profuse and even fatal hæmorrhage. In rarer cases direct ulceration of a vessel may take place before thrombosis has been effected within it, and hæmorrhage may again be the result. Vessels running in the walls of cavities are specially liable to be thus eroded; and this cause of bleeding

is not uncommon in connection with bronchiectatic cavities, and with those resulting from the ulceration of malignant growths.

SEAT AND DISTRIBUTION.—Tubercular cavities occur most frequently in the upper lobes of the lungs. The two sides of the body are affected with practically equal frequency, and both lungs are often the seats of excavation at the same time. In some instances only a single cavity may be found, and may vary in size from that of a pea to a chasm occupying a whole lobe of the lung. In other cases many cavities occur together, a whole lobe, or even more than one, being honey-combed with excavations. These may communicate one with another, and may ultimately coalesce to form a single cavity. Partial septa are frequently found in vomicae, constituting the remains of partitions which originally separated distinct spaces. Tubercular cavities in the lower lobes are not, however, very uncommon, and retention of the secretions with consequent decomposition may occur in these as in bronchiectatic cavities, which usually occupy this position.

EFFECTS.—The existence of cavities in the lung, surrounded by tissue in a condition of chronic inflammatory fibrosis, causes alteration in the shape of the chest-walls and in the relative positions of the thoracic viscera. The tendency of fibrous tissue to contract being aided in this case by the existence of hollow spaces which offer no obstacle to the process, there takes place a considerable shrinkage of the affected part. By this means the size of the cavity is reduced (although it is probable that a vomica when once formed never completely disappears), and owing to the existence of pleural adhesions the thoracic wall is drawn in and the diaphragm elevated into the chest. If only one lung is affected the sound lung of the opposite side expands so as to occupy more space and do more work (vicarious emphysema). At the same time, owing to diminished support from the shrinking lung and occasionally to the actual traction of adhesive bands, the heart is moved from its normal position and may be found beating in the left axilla if the left lung be shrunken, or to the right of the sternum in cases of right-sided cavities. In patients with old and very extensive cavities, the alteration in the shape of the thorax may be so great that actual curvature of the spine is produced, the concavity of the curve being towards the affected side.

In the majority of cases adhesion takes place between the two surfaces of the pleura over an excavated spot. Rarely in the absence of this protective process the vomica may extend and burst into the general pleural cavity, causing pneumothorax. The constant drain of pus from a chronic cavity, and the absorption of bacterial toxins from it, may finally result in the onset of amyloid (lardaceous) degeneration of other organs.

DIAGNOSIS.—The phenomena from which it is possible to infer the existence of a cavity in the lung are dealt with at length in the article on **PHYSICAL EXAMINATION**. Little can be learned from inspection of the chest, since fibrosis of the lung without excavation is capable of giving rise to great retraction of the thoracic wall. Percussion is of value in some cases. It is necessary to bear in mind that, although percussion over a cavity should, and does, give rise to a tympanitic note under favourable circumstances, in the great

majority of instances this resonance is modified by the existence of a layer of solidified lung between the chest-wall and the cavity, and also frequently by thickening of the pleura overlying the affected area. It is thus only in cases of very superficial cavities that tympanitic resonance is obtainable. Usually the normal percussion-note is impaired over a vomica, the sound obtained being often of a high-pitched 'boxy' character, which is very suggestive but not distinctive of excavation. By very vigorous percussion, the patient's mouth being open, it is possible to elicit the 'cracked-pot' sound; but it is inadvisable to use the amount of force needful to elicit this phenomenon, owing to the danger always existing of setting up hæmorrhage from some weakened or aneurysmal vessel. In the case of very large cavities with fluid contents, alteration of the posture of the patient from the vertical to the horizontal position, or *vice versa*, may cause changes in the percussion-signs, comprising alterations both in the respective areas of resonance and dullness, and in the quality of the sound obtained. The most characteristic sign audible on listening over a cavity is the so-called cavernous or amphoric breath-sound. This differs from bronchial or tubular breathing in the deeper pitch of the note and in possessing a certain musical quality which has been compared to the sound obtained by blowing across the neck of a bottle. Vocal sounds are increased over a cavity, and occasionally a peculiar resonating effect is produced within it. Whispering pectoriloquy is also very marked, but is not distinctive of excavation, as it may be heard equally clearly over consolidated lung. Air passing through liquid contained in a cavity gives rise to bubbling sounds (râles) of peculiar hollow metallic quality, and the dropping of fluid from the roof of a large vomica may occasionally produce 'metallic tinkling.' The bell-sound may also be heard over large empty cavities on tapping one coin upon another placed against the chest-wall. When the patient coughs splashing of the fluid in the cavity may result and be audible to the observer, and the sound of the cough may like the voice be resonated in the cavity. At the end of the effort of coughing a peculiar suction-sound ('post-tussic suction') may be heard over a vomica, comparable to that produced by the sudden expansion of a wet india-rubber ball.

It must be distinctly understood that the phenomena just enumerated do not occur in the case of all cavities, some or all of them being absent in the great majority of instances. It is probably impossible to ascertain the existence of a cavity less than one inch in diameter, and spaces even of this size may be entirely latent if deeply situated. The two most valuable signs are probably the 'boxy' percussion-note and cavernous breathing. If the bronchus leading to a cavity become blocked, all characteristic signs on auscultation will necessarily be absent.

PROGNOSIS.—No patient in whom a pulmonary cavity exists can be said to be free from danger. The principal risk is always that of the occurrence of hæmorrhage, since it is impossible to make sure of the absence of aneurysmal dilatation of vessels crossing the cavity, while further ulceration of the walls leading to vascular erosion may at any time occur. Apart from this danger, the outlook is not necessarily bad. It is now well established that in

tuberculosis: arrest of the disease may take place at any stage, and that even after extensive excavation has occurred the malady may become quiescent and the patient recover a fair measure of health and activity. In individual cases judgment as to the probable future course must be based upon a review of all the circumstances. Gain of weight, absence of fever and sweating, good digestion, and regular sleep point to quiescence of the disease. Long previous duration apart from signs of marked deterioration of health is in favour of continued chronicity. The presence of some cough and expectoration in such cases is not necessarily of evil import, since a cavity may continue to secrete for an indefinite period. Even the presence of tubercle-bacilli in the sputum is not of necessity evidence of active tuberculosis, since it seems that these organisms may continue to exist as saprophytes after they have ceased to do active mischief.

TREATMENT.—In cases with tubercular excavation of the lung, the treatment is that of the general condition (*see* PHTHISIS), and no special modification need be introduced owing to the existence of a cavity. When the disease has reached this stage, however, and is still active, it is not advisable to send the patient away from home either for a sea-voyage or for residence at a distance, on account of the danger of hæmorrhage. When the disease has become quiescent, cases with cavities may be much benefited by residence in such climates as permit of continuous life in the open air without danger of chill. Wintering abroad is generally advisable, and it is important that those affected should not remain contented with the good results of one such winter sojourn, but should be encouraged to spend two or three winters away from home (Mitchell Bruce).

Treatment directed to the cavity itself may be necessary in cases in which the contents stagnate and putrefy. Here much may be done by means of medicated inhalations. Eucalyptus oil or terebene may be used as a moist inhalation, one drachm of either fluid being put into a pint of hot water and the patient directed to inhale the steam thrice or more daily. A kettle of water containing a small quantity of one of these substances kept simmering in the sick-room is of the greatest service in rendering the atmosphere around the patient tolerable to others. Dry inhalations may be given on an oronasal respirator, and may consist of a few drops of a mixture of equal parts of spirit of menthol, oil of eucalyptus, and spirit of chloroform, used for half an hour three times a day or oftener. In basal cavities, the factor of which does not yield to these remedies, intralaryngeal injections may be practised with apparent benefit. The injection is made through the glottis with a special curved syringe, guided by the laryngoscopic mirror, the patient being directed to lean over towards the affected side, to ensure gravitation of the fluid towards the seat of the cavity. A solution of menthol in olive oil forms a very suitable fluid for such injection. Injections by means of a hypodermic needle passed directly into pulmonary cavities at the apex and elsewhere have been tried, but are not to be recommended for general use. Surgical interference is necessary in some cases of gangrene of the lung or abscesses that drain badly. It is impossible to lay down general rules as to the indications for such treatment. If very fetid expectoration continue in spite of medical remedies, and if the patient's

general condition be deteriorating owing to absorption of septic products, the question of incision and drainage of the cavity must be carefully considered. Resection of portions of one or more ribs will probably be necessary, if operation be decided upon in order to secure free drainage. In cases of quiescent cavities with resulting deformity of the chest, carefully planned and graduated gymnastic exercises are of use to exercise the muscles and lessen deformity. Residence at high altitudes is sometimes beneficial in such cases, owing to the tendency which it exerts to cause expansion of existing healthy lung-tissue. *See* CLIMATE, Treatment of Disease by.

W. CECIL BOSANQUET.

CELL (*cella*, a cell in a honeycomb; a closed chamber).—The term 'cell' was for a long time applied in anatomy to various spaces in the body large enough to be recognisable by the naked eye; hence 'cellular' tissue, a name which has been used to designate areolar or connective tissue. But the word came afterwards to be applied by botanists in an entirely different sense, namely, to the hollow, bladder-like particles of which many of the parts of plants were shown by the microscope to be composed; and the name was extended so as to apply to similar particles in the animal body. It has since been retained and used in histology in that sense, although it has long been recognised that these particles, whether in plants or animals, but especially in the latter, do not necessarily conform to the original definition of a cell, the principal factor in which was the presence of a definite cell-wall.

Cells may be either *free* or *fixed*. Instances of free cells are to be found in the white corpuscles or leucocytes which occur in blood, in lymph, and in pus, and which constitute the bulk of lymphatic or lymphoid (adenoid) tissue. As instances of fixed cells may be mentioned the various kinds of epithelial cells; the cells of the connective tissues, including cartilage and bone; the cells of nervous tissue; and those which constitute the several kinds of muscular fibres. To these may be added the cells of most tumours.

All the cells in the body can be shown to have been ultimately derived from the ovum, or egg-cell, which, after impregnation by and union with a spermatozoon or sperm-cell, divides at first into two, these again into two, and so on by a binary process of subdivision until a small mass of cells is ultimately produced. As the cells continue to multiply, this mass presently becomes hollowed out by the accumulation of fluid in its interior, and is converted into a vesicle, the wall of which is eventually found to show an arrangement of its component cells in three layers, which collectively form the *blastoderm*. The three layers are termed respectively, from without in, the *epiblast*, *mesoblast*, and *hypoblast*, or *ectoderm*, *mesoderm*, and *entoderm*, and give origin in course of development to the different tissues and organs of the body. The epiblast produces the cuticle and nervous tissues, and the essential parts of the sense-organs; the mesoblast the muscular and connective tissues, including the blood and blood-vessels; the hypoblast forms the epithelium of the alimentary canal, and of the glands which open into it, including the epithelium of the pulmonary air-passages.

Cells vary very much in size, but few are large enough to be visible to the naked eye. Every cell

in the body possesses one or more nuclei, although in some cells, in consequence of chemical alterations, the nucleus may have disappeared completely. Such cells are, however, no longer living and active, and undergo only passive changes; of the living cell the nucleus appears, at least in all the higher animals and plants, to be an essential part.

The main part of the cell, in which the nucleus is embedded, is known as the *cell-body* or *cell-substance*. In most cells it is chiefly formed by a soft albuminous material, named *protoplasm*. It is upon the presence of this material that the so-called 'vital' phenomena which are manifested by the cell obviously depend, such as the amoeba-like movements or changes of shape which are exhibited by free cells such as the white blood-corpuscles; the production, storage, and eventual expulsion from the cell of materials which are to take part in the formation of the secretions, as in the fixed cells of glands; and the internal changes, molecular or molar, which result in the wave-like transmission of impulses or movements, as is seen in the manifestations of activity which occur in muscle and nerve, and in ciliated cells. Most of these changes are or may be produced or modified by the incidence of external stimuli; and the property by virtue of which the protoplasm responds to these or other (unknown) stimuli is termed its 'irritability' or 'excitability.'

When protoplasm is examined chemically in the dead state it is found to be mainly composed, besides water, of certain forms of globulin and albumen, which do not materially differ from those which occur in fluids, such as egg-albumen and blood-serum, which exhibit none of the phenomena of life. But there is reason to believe that the molecular constitution of the protoplasm is very different during life from that which is found after death, being in the former condition of especially unstable character and undergoing changes with great readiness. It is indeed in the highest degree probable that chemical and physical changes are *continually* proceeding during life, and that the chemical changes are of two antagonistic kinds, the one kind tending to produce a building up of fresh protoplasmic substance from the proteid and other material supplied by the blood and lymph, and the other kind tending to produce a breaking down of such substance, and a formation of simpler products. To those two hypothetical antagonistic processes which proceed during life, the terms *anabolic* and *katabolic* have been applied, while to the whole of the chemical changes which go on, both in the individual cells and in the collective organism, the name *metabolism* is given.

The forms assumed by the cells are very various: thus they may be spherical, ovoidal, spindle-shaped, flattened or scale-like, columnar, stellate—in short, of any conceivable shape. Fixed cells retain the same shape for an indefinite time, or undergo only passive alterations; free cells are frequently observed to alter their shape continually by the spontaneous protrusion and retraction of processes of their protoplasm (*pseudopodia*). These spontaneous changes or amoeboid movements may, under certain circumstances, produce an actual locomotion of the cell, as is noticed to occur in the process of *diapedesis*, or passage of the white blood-corpuscles through the walls of the capillaries and venules.

Cells may lie scattered and isolated in a tissue, or they may be united by their processes into a network, as in the connective tissues, or closely packed

and joined edge to edge to form either a membranous stratum or a solid mass of cells, which may constitute the bulk of the tissue to which the cells belong, as in the epithelial tissues. Or the cells of a tissue may undergo special development and structural modification, associated with the assumption of special properties of conduction and contractility, as in the nervous and muscular tissues. In ciliated epithelium the protoplasm of the cell is prolonged at the free border into minute hair-like projections, which during life execute a spontaneous lashing movement (*vibratile cilia*).

In spite of the numerous researches which have been made of late into the structure of cells, very little is known positively regarding the structure of the protoplasm. Until a comparatively recent date it was described as entirely without structure; and in many cells, especially those of the free type, it is difficult to make out any definite appearance of structure, especially in the living condition. It is true that under the influence of certain hardening re-agents, such as alcohol and chromic acid, a reticular appearance is produced in protoplasm, but the same appearance can equally well be produced in solutions of albumen and mucin under similar circumstances, so that the reaction in question by no means proves that the apparent structure is pre-formed; and it is still the opinion of some histologists that protoplasm is essentially structureless. It is certain, however, that in many *fixed* cells a network may be observed even in the living condition, the nodes of the network causing a characteristic finely granular appearance in the protoplasm; and most cytologists accordingly describe the living substance of a cell as being composed of a spongework (*spongioplasm* or *reticulum*), and interstitial matter or matrix occupying the meshes of the spongework (*hyaloplasm* or *enchylema*). Whether the vital phenomena exhibited by protoplasm depend upon the spongioplasm or the hyaloplasm, or belong to both these parts of the living substance, is entirely unknown.

The protoplasm of a cell may contain other materials embedded in its substance, which may either have been formed by the protoplasm from materials obtained from the blood, or in the case of 'free cells' may have been taken bodily into the cell-protoplasm by aid of the amoeboid movements of which these cells are capable (inception of particles). These materials may be in the form of granules of albuminous, fatty, or carbohydrate nature, or of globules of watery fluid containing substances in solution (vacuoles). Such non-protoplasmic ingredients of the cell-substance, when occurring within the cell as ordinary products of its nutrition, are collectively termed *deuteroplasm*. This term also includes such portions of protoplasm as may have become converted within, or at the surface of, the cell into non-living material, as when the external layer of protoplasm becomes transformed by physical and chemical alterations into a firmer and more resisting covering to the cell, which thus becomes invested with a *cell-wall*. Pathological changes in cells are usually due to abnormal chemical transformations of the protoplasm, which in this case are usually termed *degenerations*, such as the *fatty*, *mucous*, and *colloid*.

The protoplasm of many cells, especially of free cells, such as the white blood-corpuscles and the marrow-cells, contains *granules*, embedded in the protoplasm, which are of a proteid or nucleo-proteid

nature and appear to be special products of the cell-metabolism. They are not, however, all chemically identical, for while some are stained more readily by basic dyes (*basophile granules*), others take up acid dyes (*oxyphile granules*), while others react to both basic and acid dyes (*amphophile*), and others again most readily to neutral stains (*neutrophile granules*).

Every cell in the body possesses at least one nucleus, but some cells may have two or three nuclei; and others, such as the giant-cells which are met with in normal red marrow and in certain pathological formations, may contain a large number. The nucleus of a cell is usually spherical; it is situated near the centre of the cell, and appears to possess the function of presiding over the nutritive changes of the protoplasm, as well as that of initiating the division of the cell.

Most nuclei have a well-marked reticular structure, which is visible even in the living cell unaltered by reagents. The filaments of the network have the property of becoming darkly stained by hæmatoxylin and many other staining reagents; hence the substance of which they are composed has been termed *chromatin*, to distinguish it from the part of the nucleus which remains unstained, and which is termed in contradistinction *achromatin*. The filaments are aggregated at the surface of the nucleus into a closely reticulated membrane which serves to limit the nucleus externally. The nodes of the network, as seen in optical sections of the nucleus, give the latter a coarsely granular appearance, especially because the substance of the filaments tends to become aggregated at the nodes. Besides these aggregations there are usually present in the nucleus one or two larger masses of chromatin, staining somewhat differently from the rest, and not always situated at a node of the nucleus-network. To these larger masses the term *nucleoli* is applied. In some nuclei the usual network is replaced by a sort of convoluted skein of nuclear filaments, the latter being somewhat thicker than usual, and exhibiting, when sufficiently magnified, a peculiar transversely striated appearance. This condition is, however, usually only met with in nuclei which are about to undergo division.

In many cells there has been detected in the protoplasm, usually near the nucleus, a minute particle (*attraction-particle* or *centrosome*), which stains in a special manner with certain reagents, and appears to exert an attractive influence upon the neighbouring protoplasm, which shows lines converging towards the centrosome. Prior to the division of the nucleus, the centrosome is always found to have divided, and its two parts are united by a system of fine lines or fibrils. This ultimately becomes developed into a spindle-shaped structure of considerable size, which envelops the dividing nucleus and appears to offer directing lines, along which the parts of the nuclear chromatin, after division, pass towards opposite poles of the cell. It is then known as the *directing spindle*, and each half of the original centrosome is termed a *polar particle*. This, after the formation around it of the daughter nucleus, eventually takes up a position in the protoplasm as the centrosome of the daughter-cell.

The division of the nucleus was formerly believed to occur by a simple process of fission, preceded by the division of the nucleolus. It is doubtful, however, if this simple process of so-called *direct* division occurs regularly in many cells. In nearly every case

of cell-division, both in normal tissues and in pathological formations, the nucleus undergoes a complete series of changes, which are collectively known under the name *karyokinesis* or *karyomitosis*, and which result in the division first of the nucleus and ultimately of the cell (so-called *indirect* division). The changes which are thus undergone are as follows:—The whole of the chromatin, including the substance of the nucleoli and the membrane of the nucleus, first becomes collected into one or more filaments, which have a convoluted skein-like arrangement, the skein being at first closely wound, and its filament or filaments fine, but becoming gradually more open, and its filaments coarser. Next, it is found that the skein has become subdivided into a definite number of short filaments, which often assume a bent V-shaped form, with the apices of the V's directed towards the centre of the nucleus (*aster-phase*). The V's then undergo an alteration in relative position, becoming interlocked at the equator of the now elongated nucleus, and having their apices directed towards the two poles. At or before this *equatorial phase* of karyokinesis the filaments undergo a process of longitudinal cleavage, so that there are now twice as many as at first. The resulting finer V-shaped filaments then begin to pass into two groups, which gradually tend towards either pole of the nucleus, assuming as they pass thither a radiate arrangement, with the apices of the V's towards the centre of each group. This is the *diaster-phase*. Finally, in each of the two groups, the V-shaped filaments unite end to end to form a skein, which subsequently becomes converted into a network, and the formation of the daughter-nuclei may now be regarded as complete. Around each one the corresponding half of the protoplasm of the cell becomes aggregated, so that two daughter-cells have become formed by division of the parent-cell.

While these changes are going on in the chromatin of the nucleus, others are proceeding in the achromatin substance. Within this the spindle-shaped system of fibrils connected with the divided centrosome makes its appearance, both the poles and the equator of the spindle corresponding with those of the nucleus. At each pole of the spindle is the spherical particle termed the *polar particle*, and from this particle other fine fibrils radiate into the adjacent protoplasm, so that a system of achromatin-fibres penetrates not only through every part of the nucleus, but throughout the greater part of the protoplasm of the cell as well. The fibres of the nuclear spindle appear, as already mentioned, to serve as directing lines along which the above-described movements of the chromatin-filaments towards the poles of the nucleus occur, and the equator of the spindle determines the plane of separation both of the nucleus and of the cell.

E. A. SCHÄFER.

CELLULITIS.—Cellulitis is a term used to denote inflammation of the great planes of cellular or connective tissue. The subcutaneous tissue is most often affected: occasionally the intermuscular, mediastinal, pelvic, and other deep layers.

Cellulitis may be *acute* or *chronic*, *circumscribed* or *diffuse*, *non-suppurative* or *suppurative* (see **ABSCESS**: Acute Diffuse Suppuration).

ÆTIOLOGY.—Acute non-suppurative cellulitis is the result either of infection by organisms (usually the pyococci) which fail for one reason or another to

induce suppuration (*see* ABSCESS), or of the entry of some irritant, like urine, into the tissues. The organisms may be (1) inoculated directly through a wound—even the smallest puncture or abrasion; or (2) conveyed to the part by the lymphatics or the blood-vessels from some distant source of absorption, their deposit being often localised by some simple injury; or (3) they may spread to the connective tissue from some adjacent or embedded structure, e.g. from the skin, lymphatic gland, kidney. Alcoholism, albuminuria, and general depression of the resisting power favour all inflammations.

SYMPTOMS.—These are the redness, swelling, heat, and pain of inflammation: more or less widespread, and more or less marked according to the vigour of the inflammatory reaction and superficiality of the process. When the subcutaneous tissue is affected, the part usually ‘pits;’ not so when the inflammation is entirely subfascial. Impaired function and fever are present, but vary much in degree.

Perfect resolution and subsidence of symptoms is the usual ending; but in some cases as the more acute process subsides, and in others, often of unknown ætiology, which have throughout run a chronic course, a less favourable result is obtained; and thickening of tissues, matting together of parts such as tendons and their sheaths, contraction and shrinking of the connective tissue causing marked and persistent displacement of organs (e.g. uterus) may occur (*see* PELVIC CELLULITIS). Repeated slight mechanical irritation will result in the formation of long-lasting thickening. Rarely, as the result of infection by certain very intense irritants, or of greatly impaired tissue-resistance (e.g. in an anasarctous limb), gangrene may occur without any suppuration.

DIAGNOSIS.—The one difficulty is to determine whether or not suppuration is occurring. It is indicated by increasing intensity of the physical signs at one or more spots. Absolute certainty is not of great importance, because if there is good ground for suspecting pus, incision (aseptic) will be beneficial.

TREATMENT.—In the first place disinfect with phenol any source of absorption. Elevate the inflamed part as much as possible and give local rest, or general, if the case is severe. Compression by bandage over cotton wool in large quantities is often valuable; in other cases warm baths, fomentations, or poultices (the skin being unbroken) are more beneficial. Should gangrene threaten, incisions should be made at once and freely. For the treatment of suppuration *see* ABSCESS. In dealing with the results of chronic cellulitis, warm bathing, douching, movements, and massage are useful.

STANLEY BOYD.

CEPHALALGIA (κεφαλή, the head; and ἄλγος, pain).—Pain in the head. *See* HEADACHE.

CEPHALHÆMATOMA (κεφαλή, the head; αἷμα, blood; and ὄμα, a formative suffix indicating a tumour).

DEFINITION.—An effusion of blood occurring in newly born infants, forming a tumour upon the head; situated beneath the pericranium, upon the surface of the skull; or more rarely beneath the skull, between it and the dura mater.

DESCRIPTION.—This disease is of very rare occurrence, and must not be confounded with the *caput succedaneum*, which is an effusion of serum

external to the pericranium, and of common occurrence. The blood is generally extravasated immediately beneath the pericranium, over one of the parietal bones, most frequently the right, but it may occur over the frontal or occipital. Combined with this, or arising independently, but of extreme rarity, may be an effusion beneath the cranium. The origin of cephalhæmatoma has been attributed to a variety of causes, but is most probably due to the constriction of the margin of the os uteri during labour. It is generally observed some hours or a day after birth, as a circumscribed swelling, slightly tense and fluctuating; and its peculiarity consists in a bony circle surrounding and limiting it.

DIAGNOSIS.—These tumours have been mistaken for hernia cerebri; but their situation over the bone away from the fontanelles, the absence of pulsation, and the existence of fluctuation in cephalhæmatoma should prevent this mistake.

PROGNOSIS.—Generally the blood becomes absorbed, but occasionally suppuration occurs, or the bone may become necrosed; if beneath the skull, serious consequences, including idiocy, may ensue.

TREATMENT.—As a rule, cephalhæmatoma is not to be interfered with. If suppuration take place the pus must be evacuated.

CLEMENT GODSON.

CEREBELLUM, Lesions of.—The cerebellum is liable to the same diseases as the brain and nerve-centres generally, such as hæmorrhage, abscess, softening, atrophy, and tumours. The nature of the pathological condition is to be determined by the symptoms peculiar to each, so far as this is possible. Its locality in the cerebellum is to be diagnosed, first, by certain symptoms which are due to the cerebellar lesion as such, which may be termed the *direct* symptoms; and, secondly, by those symptoms which depend more on the influence exerted by the lesion on neighbouring or subjacent centres and structures. These latter may be termed the *indirect* symptoms.

It is by no means easy to separate these symptoms from each other, and to say how much is due to interference with the functions of the cerebellum, and how much to interference with the functions of other parts. There are few diseases which have a purely local organic or functional limitation. Hence, in order to arrive at the symptoms peculiar to cerebellar lesions, it is necessary to exclude all pathological affections which in their very nature affect the whole of the intracranial centres, such as tumours or meningitis. The most satisfactory conclusions, from a pathological point of view, are to be drawn from cases of atrophy or degeneration of the cerebellum, and, from a physiological point of view, from the results of experimental lesions of this organ in the lower animals.

The evidence from these two sources is mutually supporting.

DIRECT SYMPTOMS.—The characteristic symptoms of cerebellar disease are disorders of equilibrium, shown, on attempts at locomotion, in a reeling or staggering gait (titubation), and a continual tendency to stumble or fall over the most trifling obstacle, or on hurried movements.

These symptoms may be confounded with those of locomotor ataxy, but careful observation will show that in cerebellar disease there is no true ataxy. The movements are quite co-ordinated with each other, and are such as would instinctively be made

to prevent falling, or to preserve the equilibrium; and have none of the precipitate, irregular, and sprawling character seen in ataxy. They are not specially intensified on closure of the eyes, which is such a marked feature in ataxy. Nor are they accompanied by any of the sensory affections of ataxy, whether in the form of pains or anæsthesia.

There is no true motor paralysis in cerebellar disease as such, and the various volitional movements of the limbs can be carried out perfectly well in the recumbent posture. Sensation, general and special, is not directly affected. Nystagmus may occur as a direct symptom of cerebellar disease. It would appear as if the more pronounced nystagmoid jerks were on the side of the lesion.

Lesions of the cerebellum may be entirely latent, or not cause any obvious symptoms during life. This has been observed in cases of congenital atrophy, or when the disease has been of a slowly progressive character, or limited to one lobe. Although affections of the middle lobe are specially calculated to induce the characteristic symptoms of cerebellar disease, it by no means follows that lesions of the lateral lobes are without their localising phenomena. Of these may be mentioned: rotatory movements towards the side of lesion, more especially if the middle cerebellar peduncle is also involved, and tremors of the limbs on volitional effort upon the side of the lesion. The knee-jerks are directly affected by experimental ablation, that on the side of extirpation being at first exaggerated. In disease the state of the knee-jerks is not constant, so that this symptom is of little localising value.

INDIRECT SYMPTOMS.—*Pain in the head*, more particularly at the back, though not constantly situated there, is frequently associated with tumour of the cerebellum.

Vomiting is also very frequently observed, perhaps more commonly than in connection with disease of other parts of the brain. There is, however, no reason to regard this as due to cerebellar disease as such. As a general rule, lesions tending to encroach on the space of the posterior fossa, or to increase the pressure in this region, have a similar effect.

Hemiplegia is not uncommon in connection with cerebellar disease, particularly in cases of tumour or hæmorrhage in the lateral lobe of the cerebellum. The hemiplegia is often on the side opposite the lesion. This does not prove that the hemiplegia is due to the destruction of the cerebellar lobe, or that the cerebellar lobes have cross relations with the limbs. Experimental physiology and anatomical investigations tend to show that the cerebellar lobes are functionally related to the motor tracts on the same side. There is however no direct strand of fibres issuing from the cerebellum towards the spinal cord; the cerebello-spinal system being an indirect and uncrossed one through the nucleus of Deiters and the descending antero-lateral tract. The cerebro-cerebellar relation is on the other hand crossed, as old-standing disease or atrophy of one cerebral hemisphere is occasionally associated with atrophy of the opposite cerebellar hemisphere. The hemiplegia from cerebellar disease, whether direct or crossed, is, therefore, in all probability, due to compression or some affection of the subjacent motor tracts, which decussate at the pyramids. The fact that it occurs chiefly when the disease is limited to the lateral lobe is what might be expected on anatomical grounds.

Affections of Sensation, common and special, have been observed in cases of cerebellar disease. Diminution of tactile sensation on the opposite side of the body, when the disease is situated in the lateral lobe, may be explained by the pressure of the new-growth upon the sensory tracts in the tegmentum pontis. As regards the special senses, affections of sight have been most frequently noted. Sight is certainly not abolished by destruction of the cerebellum in the lower animals, and when blindness occurs in man in connection with diseases of this organ, it is due to secondary implication of the optic tracts as the result of neuritis.

A special feature of *tumours* of the cerebellum, more especially of the middle lobe, is a tonic rigidity of the muscles of the back of the neck, with retraction of the head, associated frequently with flexion of the forearms, and extension of the lower extremities with pointing of the toes. In these cases also, psychical affections, more particularly mental hebetude or stupor, occur as the result of secondary dropsy of the ventricles, caused by pressure on the veins of Galen and obstruction of the iter Sylvii. The symptoms then become those of hydrocephalus.

The most important indirect symptoms of localising value are paralysees of the cranial nerves. Paralysis of the fifth cranial nerve is not uncommon with symptoms of cerebellar disease, and points to a lesion of, or involving, the middle peduncle. The facial nerve also is paralysed in some cases of tumour of a lateral lobe extending towards the base of the brain. Of most frequent occurrence is paralysis of the eighth nerve, shown by deafness. Less common is paralysis of the hypoglossal nerve. As a rule paralysis of the cranial nerves shows that the lesion is upon the paralysed side. *Hæmorrhage* into the middle lobe of the cerebellum, in addition to the ordinary symptoms of apoplexy, has been frequently found to cause vascular excitement of the genital organs—in the male marked *priapism*. This symptom, of which several cases were first reported by Serres, led this observer to modify the view of Gall that the cerebellum, as a whole, was related to the sexual instinct, and to regard the middle lobe only as having any such function. The facts, however, are susceptible of a totally different interpretation, and one more in harmony with other data of physiology and pathology. There is absolutely no evidence of the slightest value in support of Gall's hypothesis.

Cerebellar Peduncles.—Cases are on record in which lesions have been found involving principally either the superior or middle cerebellar peduncles. The symptoms, in the main, agree with those observed by Magendie on section of the middle peduncle in the lower animals. The chief effect of this lesion was to cause an irresistible tendency to roll over towards the side of lesion, and this has been amply confirmed by recent experimental work upon monkeys. Together with this rotatory disturbance of the equilibrium, a peculiar distortion of the optic axes was observed, the eye on the side of lesion being directed downwards and inwards, the other looking upwards and outwards. Other symptoms of importance following this lesion were tremors or voluntary movement, such as are seen in cases of disseminated sclerosis.

In a case described by Curschmann, along with appearances of basilar meningitis, which somewhat complicated the case, there was found a focus of softening, surrounded by capillary hæmorrhage,

in the right *superior cerebellar peduncle*. The symptoms observed in this case were a rotatory distortion to the right side, to which position the patient invariably returned when resistance to this movement was withdrawn. There was no motor paralysis, nor was there any distortion of the optic axes. In Bannister's case the patient lay with the head and body in a forced position towards the right side, the lesion being a small hæmorrhage in the right superior peduncle. A case has been put on record by Nonat of apoplectic extravasation into the right *middle peduncle* of the cerebellum and right cerebellar hemisphere. In this case the head and trunk were twisted towards the right side, and the ocular symptoms were also present, the eyes being immovable in a position of skew deviation. Other cases are on record in which the cerebellar peduncles have been involved in more extensive lesions; but the symptoms, though not opposed to those above related, are incapable of differential analysis. The special diagnostic symptoms, therefore, of lesion of the cerebellar peduncles are what are frequently termed 'forced movements' (*Zwangsbewegungen*), or distortions of the normal axis of the trunk. The exact direction of the distortion, in consequence of lesions specially limited to one or other peduncle on the right or left side respectively, is somewhat doubtful, though as a rule it has been found towards the side of lesion. In lesion of the middle peduncle the fifth nerve is most likely affected.

The effects of lesion of the *inferior cerebellar peduncle* are limited to the results of experimental lesion. These are chiefly 'forced movements' and a tendency to rotation to the side of lesion, with adduction of the limbs on the same side, and abduction on the opposite side. In a case of Brissaud's, the cerebellum was also slightly implicated, and the patient showed, in addition to a cerebellar gait, increasing deafness of the ear on the side of the lesion.

CEREBRAL DIPLEGIA.—SYNON.: Birth-palsy; Little's disease.

DEFINITION.—An affection that is usually congenitally installed, but which may also be due to post-natal causes; whose manifestations commonly date from or soon after birth; whose chief characteristics are bilateral rigidity, motor weakness, and, it may be, perverse movements; and in whose symptomatology are included all degrees of mental deficiency down to complete idiocy. The name 'Little's disease' is commonly limited to the paraplegic form of the affection, which is also known as 'Congenital Spastic Paraplegia' and 'Cerebral Spastic Paraplegia.'

ÆTIOLOGY.—In the majority of cases the disease is congenitally determined; and although no cause can be assigned in many instances, it is possible that such cases are due to some morbid condition of the mother during her pregnancy. The maternal states that are regarded as of consequence are general ill-health, the results of over-work and

of defective feeding, neurasthenia, syphilis, specific fevers, eclampsia, blows to the abdomen, and abnormal psychic states. Failure of the physiological process of generation plays an important rôle in the ætiology of some cases, and it is noteworthy that the youngest members of large families are especially liable to be affected, while pregnancies subsequent to the birth of a diplegic child may result in still-births. Consanguinity of the parents has been noted in some cases, and hereditary transmission of the disease from a parent to her offspring has occurred. There is one form which is met with almost exclusively in the Hebrew race.

Disorders of parturition account for some cases, though the frequency of this cause appears to have been over-estimated. The causes included in this group are: premature birth, prolonged labour, precipitate labour, instrumental or other injuries at birth, and asphyxia neonatorum; although the evidence that premature birth is a cause is not convincing.

Post-natal affections of the child claim only a subsidiary place in the ætiology of cerebral diplegia; nevertheless, acute specific fevers, encephalitis, vascular lesions, and epilepsy appear at times to be in direct causal relationship. It is, however, possible that, in at least some of the cases, these post-natal factors may only serve to bring out a congenitally installed disease.

SYMPTOMS.—Several clinical forms of the affection are recognised according as rigidity and motor weakness or spontaneous movements dominate the picture; according to the distribution of the rigidity and motor weakness; and according to the degree of mental impairment that is present. The forms are: (1) Generalised rigidity, (2) Paraplegic rigidity, (3) Bilateral athetosis, (4) Choreiform diplegia, and (5) Profound mental defect associated with slight generalised rigidity. Various combinations of the different varieties are met with; but the cases of generalised rigidity and those of paraplegic rigidity far outnumber all other forms of the affection.

The symptoms usually date from birth; stiffness of the limbs may first attract attention, or, when present, athetoid or choreiform movements may first be noticed. When the defect is slight, nothing abnormal may be observed until the child commences to crawl or walk. In other cases mental deficiency, including backwardness in talking, is the first prominent symptom. Concomitant congenital defects, such as strabismus, nystagmus, or pes cavus, may supply a clue to the true nature of the malady.

When the disease is post-natal in origin it is commonly ushered in by febrile manifestations, and, it may be, vomiting and convulsions. The rigidity in the limbs develops in a few days, or, when there have been convulsions, paresis may precede the rigidity. In other cases there are no premonitions; the rigidity and motor weakness gradually appear without obvious cause, or they may follow some injury to the head.

Although motor weakness and rigidity are both present, the latter is usually greater than the loss of motor power. All parts of the body may be affected, but not in equal degree; the legs suffer most and are alone affected in the paraplegic form; the arms suffer less, and the face least of all. The arms may, however, be more affected than the legs in some cases, and still more rarely the face may be more affected than either the arms or legs. All

movements are executed slowly and in a clumsy manner, and they may be further hampered by contractures. Patients capable of walking may do so on their toes, as contracture of the calf-muscles may prevent the heels from reaching the ground; the knees may be partly flexed owing to similar contracture of the hamstrings, and spasm of the adductors of the thighs may occasion cross-legged progression. In pronounced cases of generalised rigidity the sitting posture may be impossible, and in the paraplegic form the legs may remain extended when the patient sits. Various attitudes are assumed in cases of generalised rigidity. The patient may be curled up into the smallest possible space, with the head and trunk bent forward, the elbows pressed to the sides, the forearms crossed over the chest, and the legs drawn up in extreme flexion at the hip and knee. Or an 'attitude of adoration' may be assumed, with the head drawn back, the eyes staring, lordosis of the spine, the elbows pressed to the sides, and the hands supinated below the face, while the legs are rigidly extended. Instead of either of these postures, all the limbs may be rigidly extended, and the forearms supinated: more rarely they are markedly pronated. Perverse movements of different kinds may be seen, notably facial over-action, grimaces, athetoid or choreiform movements, and intention-tremor; and it is especially the upper limbs that are thus affected. One or other form of spontaneous movement may be present alone, or they may be combined, while rigidity and paresis are usually only slight in such cases. In athetosis the movements are slow and are most marked in the distal portions of the limbs; the face is often similarly affected, and even the tongue may participate. In choreic diplegia, on the other hand, the movements are quick and shock-like, resembling those seen in myoclonus multiplex; they are most marked in the proximal segments of the limbs, and they are only rarely seen in the face. The muscles are unduly firm in some cases, and if athetosis is a feature they become hypertrophied; but in the late stages of severe generalised rigidity the muscles waste, a feature that is especially characteristic of the form of diplegia that is met with in Jews. Fibrillary tremors of the muscles are common, especially in adult cases.

The tendon-jerks are increased, though they are often difficult to elicit owing to the great rigidity of the limbs, and it is not usual to obtain ankle-clonus. Babinski's sign is almost invariably present. Cutaneous sensibility and the muscular sense are not impaired. The sphincters are not affected. The pupils may be unequal, and may react sluggishly to light. Coarse spontaneous nystagmus is common, and convergent strabismus is present in a good many cases. Primary optic atrophy is also frequent, and is constant in the form of diplegia that occurs in Jews; another characteristic of this form of the disease is a whitish-grey patch in the macular region about twice the size of the optic disc, with the fovea centralis appearing as a cherry-red spot in the centre of the patch. When affected, the face may have a 'starched' appearance owing to lack of change of expression; the palpebral fissures are wide, the lids retracted, and the mouth usually widely open. The tongue is often unduly large, and can only be protruded with difficulty. The arch of the hard palate is commonly high and narrow. Difficulty in swallowing is common, and dysphonia or stridor may occur.

There may be no mental impairment, or all degrees of defect may be met with down to complete amentia; but there is no relationship between the degree of mental impairment and the amount of physical disability: the former may be great, while the latter is slight, and *vice versa*. The patients are as a rule placid; but they may be mischievous, irritable, and passionate. The child may never learn to speak; it may lose this faculty if it has already been acquired; or it may be backward and may ultimately only speak very indistinctly. Convulsions may occur, and are more common in cases of generalised rigidity than in cases of spastic paraplegia; they are also frequent in cases with choreiform movements and in bilateral spastic hemiplegia. Permanent epilepsy may be established in some of the patients. Deformities of the skull are common, notably microcephaly in congenital cases; while in some there is hydrocephalus and in others the skull is asymmetrical. Deformities of the spine are also frequent, especially kyphosis; but there is often scoliosis and sometimes lordosis. Pes cavus is often present; sometimes there is talipes equino-varus, and sometimes genu recurvatum. The development of the affected parts is retarded, though this is less easy to determine than in infantile hemiplegia where there is the normal side for comparison.

MORBID ANATOMY AND PATHOLOGY.—The morbid changes found are not always the same, and they moreover differ according as an examination is made while the initial lesions are still in existence, or when only the secondary consequences of these remain. The brain may show no abnormality to the naked eye, although degenerative changes are evident on microscopical examination. There may, on the other hand, be pronounced atrophy of the convolutions, with a worm-eaten appearance of their surface, and increase in the width of the sulci. Instead of being uniform, however, the atrophy may be limited to some parts, so that a knobbed appearance results from alternate shrinking and projection of the convolutions. Or the changes may be even more gross, and porencephalic cavities may be present.

Cases that have come to necropsy at an early stage have shown marked degeneration of the neurons of the cerebral cortex, without evidence of interstitial or inflammatory changes; whereas those examined years after the onset of the disease have shown sclerosis of the brain, with increase of the glial tissue, thickening round the blood-vessels, disappearance of the nerve-elements, and, in some cases, porencephalus. The lesions are superficial, whereas in bilateral spastic hemiplegia they are deep-seated.

There are various views as to the probable nature of the initial lesion in cases of diplegia; but it appears probable that primary degeneration of the neurons of the cerebral cortex accounts for most cases, and that the degeneration is due to the action of some toxic agent. Other lesions to which the condition has been attributed are encephalitis, meningeal hæmorrhage, hæmorrhage into the substance of the brain as a result of trauma or asphyxia neonatorum, embolic occlusion of branches of the middle cerebral arteries, and thrombosis of cortical veins, and of the longitudinal sinus. Finally, there are the views that some cases of cerebral diplegia are due to arrest of development, and that premature birth before the pyramidal tracts are fully developed accounts for others.

The pyramidal tracts in the spinal cord show a variable amount of descending degeneration in most cases; but in a few instances they are said to have been normal. These tracts have also been absent, which suggests that the disease of the brain occurred before the pyramidal fibres had developed; but in other cases they have been merely reduced in size, possibly as a result of a lesion limited to part of the motor areas occurring at an equally early period of development.

DIAGNOSIS.—Several affections may be confounded with cerebral diplegia. In *double hemiplegia* paralysis is in excess of rigidity, the arms suffer more than the legs, and defective development of the affected parts is more pronounced. Competent observers state that *disseminated sclerosis* occurs in children; but a large proportion of the supposed cases have probably been cases of cerebral diplegia. *Friedreich's disease* usually develops later in childhood; there is no spasticity, and the knee-jerks are nearly always absent. *Hereditary cerebellar ataxy* does not give rise to symptoms until still later in life, and, except that the knee-jerks are increased, there are no spastic phenomena; optic atrophy is a constant feature. *Family spastic paralysis* appears later than cerebral diplegia, and does not give rise to any symptoms that indicate affection of the brain. In *compression-paraplegia from spinal caries* the distinction is easy; cerebral symptoms are here absent, there is usually anaesthesia and loss of control over the sphincters, and tenderness and angular deformity of the spine are common.

PROGNOSIS.—The course of the disease varies in different cases; in some it is progressive and terminates in death, a result which is almost constant in the form that occurs in Jews, and which is common in cases of severe generalised rigidity. Instead of this the disease may reach a certain stage and then remain stationary; and in a third group there may even be some amelioration after a time, a result that is especially likely to occur in the paraplegic form and in cases of slight generalised rigidity.

TREATMENT.—Careful nursing, warm clothing, and proper feeding are essential. Cod-liver-oil, extract of malt, and cream are all useful as foods, and some preparation of iron is the most suitable tonic. No effort should be spared in training the child so as to improve its mental and physical powers. Where there is much cerebral defect special training is required by a person accustomed to teach children who are mentally deficient. Massage, passive movements, and appropriate gymnastic exercises are of great value in improving the physical development, and in preventing deformities, which must further be guarded against in every possible way. When deformities have already occurred much good may still be done by regulated exercises, passive movements, and slow extension or division of the contracted tendons.

CESTODA.—See ENTOZOA.

CHALICOSIS (χάλις, gravel).—SYNON.: Sili-cosis, Stone-mason's phthisis. See PNEUMOCONIOSIS.

CHALK-STONES.—This name is applied to the deposits which are formed in connection with the gouty diathesis, especially in the joints. They are thus denominated from their appearance and physical characters, in which they more or less resemble chalk; but in their chemical composition they are entirely different, consisting mainly of urate of sodium. See GOUT; and CONCRETIONS.

CHALYBEATE WATERS (*chalybs*, steel).—Mineral waters which contain iron. See MINERAL WATERS.

CHANCRE (Fr. *chancre*).—Hard chancre is the initial manifestation of syphilis. See SYPHILIS. For Soft chancre, see VENEREAL DISEASE.

CHANGE OF LIFE.—SYNON.: Climacteric epoch; Sexual involution; Fr. *Ménopause*; Ger. *Menstruationsende*.

DEFINITION.—The time of life in a woman when the functions of the uterus and ovaries cease, menstruation terminating—a period when disease of these organs is especially prone to occur, and when various constitutional disturbances are almost certain to arise.

ANATOMICAL CHARACTERS.—Great changes occur in the sexual organs—the ovaries lose their smooth outline, and after a while become shrivelled up, occasionally only a trace of them remaining; the Fallopian tubes diminish in size, and sometimes become obliterated; the walls of the uterus atrophy, its cavity becomes much smaller, and the cervix disappears altogether.

SYMPTOMS.—The term 'change of life' is used among women very widely to signify everything which affects them at this critical time. It is so rare for the transition from activity to inactivity to take place without some disturbance locally, or constitutionally, that women are apt to neglect seeking advice for symptoms which should demand careful treatment, believing as they do that it is natural to suffer in such ways at 'the change.' There is no fixed period for the climacteric epoch, though roughly it may be said to occur between the ages of forty-five and fifty. Certain causes are apt to determine the time—among these are parturition and lactation, febrile attacks, such as typhus or acute rheumatism, profuse hæmorrhages, fright, &c.

The symptoms vary much. In some women the change is abrupt, menstruation ceasing all at once after perfect regularity; in others and more frequently, the change is prolonged, the catamenia being irregular for many months, and varying as to periodicity and quantity. Frequently, after a long interval, a profuse flow with clots occurs, and this is very often attributed to a miscarriage. This loss is frequently beneficial, and if it do not take place, and if relief be not derived from vicarious discharges, such as bleeding from piles, the excess of blood

gives rise to headaches, flushes, vertigo, and a host of other unpleasant symptoms. The balance between the nervous and circulatory system is upset; irritability of temper, hyper-sensitiveness, and all sorts of fancies arise, or depression sometimes amounting to melancholia ensues. If germs of disease exist, the uterus is especially prone at such times to develop them, so that carcinoma, fibroid disease, and polypus frequently present their first symptoms at this epoch. The importance, therefore, of an early examination cannot be too forcibly dwelt on, or the mischief of delay from considering the abnormal condition as typical of 'the change of life,' and as a natural consequence, which will right itself. At these times pruritus of the vulva, vascular growths at the orifice of the urethra, and cutaneous eruptions are especially likely to occur. There is a tendency to grow fat, and to become coarse; hairs frequently appear on the face. The breasts often become very large and pendulous, and this, with the increase in the size of the abdomen from flatus, and the deposition of fat in its walls, together with the cessation of menstruation, not infrequently gives rise to the supposition of pregnancy. To this imaginary state the term *pseudocyesis* has been applied, and it is often almost impossible to set aside the opinion of the woman regarding her supposed condition. The headaches, neuralgia, loss of memory, and nervous symptoms appear to be due to disturbance in the ganglionic system of nerves, with which the uterus and ovaries are largely supplied. If insanity arise, the most common form it assumes is hypochondriasis or melancholia.

TREATMENT.—This must be directed to regulating the secretions. Generally constipation, previously troublesome, becomes aggravated; and portal congestion frequently occurs. Saline purgatives are especially beneficial, and these may be administered in the form of mineral waters, such as Rubinat, Hunyadi János, Condal, or Friedrichshall. Blue pill with aloes is often very useful. The headaches and reflex nervous symptoms may be best combated by the administration of bromide of potassium, and this drug appears to act as a direct sedative to the sexual organs, besides diminishing the amount of blood determined to them. Occasionally, bleeding from the arm or cupping gives great relief. Attention must above all be paid to the diet. It should be plain and unstimulating: beer and spirits should be prohibited, and only light wines, if any, allowed. Tepid baths are useful. Late hours, heated rooms, and excitement of all kinds should be avoided. If local troubles arise, they must be treated according to their indications. It is clearly impossible to map out any empirical line of treatment for a condition in which the symptoms are so variable.

CLEMENT GODSON.

CHAPPED NIPPLES.—See BREAST, Diseases of; and NIPPLE, Diseases of.

CHAPS.—SYNON.: *Rhagades*; *Rimæ*.—Cracks or fissures of the skin occur where the integument has lost its elasticity and become hardened by infiltration. *Rimæ* not infrequently extend deeply and may bleed, and are then very painful. Their favourite sites are the hands and wrists in cold weather, the lips, and the skin around joints. The treatment for chaps consists in protection from the atmosphere; careful drying after previous thorough inunction with glycerine. The skin will thereby

be kept elastic and moist. Glycerine of starch, glycerine and rose-water, 'cold cream,' and hazeline-cream are also efficacious remedies.

CHARCOT'S DISEASE.—See TABES DORSALIS.

CHARCOT-LEYDEN CRYSTALS.—Colourless octahedral crystals found principally in cases of leucocythæmia (blood and sputum), and of bronchial asthma (sputum). They contain phosphoric acid combined with a base, generally called 'spermine.' The crystals are believed to be identical with those obtained by the evaporation of normal semen.

CHEIROPOMPHOLYX.—See DYSIDROSIS.

CHELOID (χηλή, a claw).—SYNON.: Keloid; Alibert's Keloid; Cheloma; Fr. *Chéloïde*; *Cancroïde*; Ger. *Keloid*; *Knollenkrebs*. The phonetic spelling 'keloid' has given rise to false derivations from κήλη, a tumour, and from κηλís, a stain or mark.

DEFINITION.—A disease allied to tumour-formation, causing overgrowth of scar-tissue.

DESCRIPTION.—Cheloid starts as a small rounded excrescence of a white or pink colour, abruptly elevated above the surrounding skin. This increases slowly in area and tends to throw out irregular lateral projections, which have been compared to claws. As it grows the centre of the cheloid-nodule may become slightly cupped, and its surface puckered owing to contraction of the fibrous tissue of which it is composed. The edges are often hyperæmic, and enlarged vessels may be visible coursing over the tumour. The growth arises in the scar caused by some injury, which may be so slight as to have escaped previous notice: thus not only the scars of wounds or burns may be affected, but also those left by leech-bites, acne, small-pox, or the operation of piercing the ears for adornment with ear-rings. The commonest seat of cheloid is over the sternum, but any part may be affected. The tumour when it has once appeared tends to increase slowly for an indefinite time, but spontaneous disappearance may occur. The growths are often tender on pressure and may be the seat of more or less severe pricking or stabbing pain. They may be multiple and are occasionally distributed symmetrically, suggesting a nervous origin.

Cheloid was formerly divided into two varieties, the 'true' and the 'false,' the former appearing spontaneously, the latter only in pre-existing scars. It is, however, probable that in the apparently spontaneous cases the original lesion was so minute as to be overlooked. The term 'cheloid' was applied by Addison to the condition now known as morphea or localised scleroderma, but this confusion of terms has been abandoned.

PATHOLOGY.—The process of formation of a cheloid-growth consists in a multiplication of connective tissue-cells along the course of the blood-vessels. Appearing first as round cells, the new elements develop into bands of fibrous tissue. Microscopically vessels may be found affected at considerable distances from the actual growth. This is situated in the corium, the epidermis and papillæ being at first intact; later on the skin becomes stretched over the tumour and the papillæ may disappear, but the epidermis remains uninvolved.

TREATMENT.—This is unsatisfactory, as the growth generally returns after removal: occasionally however this may be successful if the knife be carried very wide of the tumour. Deep transverse incisions into the growth have been recommended. Continuous pressure may be tried in parts which admit of this treatment, but care is necessary to prevent the occurrence of ulceration. Electrolysis has proved effectual in some cases in causing disappearance of cheloid-nodules and appears worthy of more extended trial. Good results have seemed to be due to inunction of mercurial ointment, but in estimating the value of treatment it is necessary to bear in mind the fact that these growths may in some cases disappear spontaneously. If the pain in the cheloid is severe, injections of cocaine into the neighbouring tissues may afford relief.

W. CECIL BOSANQUET.

CHELTENHAM, in Gloucestershire.—Common salt waters. See MINERAL WATERS.

CHEMOSIS (χῆμη, a hole).—A swollen condition of the conjunctiva, caused by effusion into its tissue around the cornea, which thus appears as if placed in a hole or hollow. See EYE, AND ITS APPENDAGES, Diseases of.

CHEMOTAXIS (χημεία, chemistry; and τάξις, arrangement).—The property possessed by certain cells and fluids of attracting or repelling other cells. See IMMUNITY; and PHAGOCYTOSIS.

CHEST, Deformities of.—Under this head are included all deviations in shape from the normal chest.

Deviations from the shape of the typical thorax are appreciable by careful physical examination. Of the various methods employed for this purpose, by far the most valuable are inspection and palpation. Although in some few cases it may be important to determine the exact amount and nature of the deformity by a measuring tape, calipers, or cyrtometer, there are very few deviations in shape or size of the thorax, the degree of which cannot be sufficiently estimated for clinical purposes by the eye and hand.

Deformities of the chest may be due either to abnormality of the parietes, or to disease of internal structures.

DESCRIPTION.—Deviations from the form or size of the typical thorax may be either *general* or *local*—that is, the abnormality may involve the whole thorax, or a part only.

1. General Deformities.—**1. General Diminution.**—The chest may be too small—that is, diminished in all its diameters without being in other respects deformed. This is due to an increase in the obliquity of the ribs. The angle formed between each of the true ribs (excepting the first) and its cartilage is more acute than normal. The intercostal spaces of the true ribs are widened about the junction of the ribs with their cartilages, and at the same time the ribs posteriorly are approximated more closely to each other, the closeness of the approximation being in proportion to the diminution in the size of the thorax. The vertical diameter of the thorax is lessened by an increase in the height of the arch of the diaphragm. The very oblique position of the false ribs, and the height to which the diaphragm rises into the chest, cause several of the false ribs to lie in contact with the diaphragm,

and thus no portion of lung is under these ribs: they are, practically speaking, no longer part of the chest-walls. The sub-costal angle is diminished in proportion to the diminution of the size of the thorax—that is, to the obliquity of the ribs. The obliquity of the ribs also causes the shoulders and the sternal ends of the clavicles to droop, and at the same time to incline forwards; the upper part of the scapula is carried by the shoulder forward, the inferior tilted backward.

General and symmetrical diminution in the size of the thorax has only one cause, namely, small size of the lungs. Small lungs may be congenital, due to developmental peculiarity; or the consequence of atrophic degenerative changes incident to age. In both these cases the lungs are, in relation to the length of the ribs, disproportionately small, and, as a necessary consequence, the relatively too long ribs are arranged more obliquely than they are in a well-formed chest, and the diaphragm is pushed by the abdominal organs higher into the thorax. When the small size of the lungs is due to atrophy, the supra-clavicular fossæ are deepened, and the vertical diameter of the chest proportionately diminished. In advanced life the congenitally small lungs are frequently reduced still further in size by the super-vention of atrophic emphysema. It is the congenitally small lungs of childhood which are prone to become the seat of tuberculosis in youth, and the subjects of atrophic emphysema in old age.

2. General Enlargement.—The thorax may be too large, increased in all its diameters, without being otherwise deformed. It is simply bigger than it should be, having regard to the height of the subject.

When the thorax is abnormally large, the ribs are placed more horizontally than they are in the normal thorax. The angle formed between each rib and its cartilage is greater than in health; while the intercostal spaces, especially the lower, are widened, and the ribs less closely approximated, the arch of the diaphragm is lessened in depth, and a considerable mass of lung lies under the lower false ribs, between them and the diaphragm. The chest is increased in all its diameters. The shoulders are raised. The sub-costal angle is greater than natural.

Increase in the size of the whole thorax has but one cause, namely, increase in the size of the lungs. General and fairly uniform increase in the size of the lungs is the consequence of disease, and of one disease only, namely, hypertrophic emphysema. When the increase in size of the thorax is moderate in degree, this is effected by the altered position of the ribs; but when the lung-disease is extreme, then a certain amount of the enlargement is caused by pressure on the inside of the chest during the violent expiratory efforts of severe cough.

3. Irregular General Deformities.—In the deformities above described the antero-posterior and the lateral diameters retain more or less perfectly their normal proportion—both are increased or both are diminished; in the former case the chest is on the whole more barrel-shaped than natural, but the deviation from the normal form is not considerable. If, however, the chest-walls are from any cause unduly soft or unduly rigid, then the actually or relatively soft portions will fail to expand or may actually recede during each inspiratory act, and local deformity of the chest follows. The diameter of the chest at the part where the absolutely

or relatively soft portion of the parietes is placed will be diminished. The special deformities of the chest which result are due, therefore, primarily to the state of the parietes, and are not, as those previously described, secondary to conditions of the lungs themselves.

a. Diminution in the antero-posterior diameter of the thorax.—The antero-posterior diameter of the thorax is frequently less than that of the normal thorax, the lateral diameter being proportionately increased. The chest has an oval form—it is flattened from before backwards.

The thorax flattened from before backwards is usually associated with small lungs, but the mechanical cause of the flattened form is the want of full resisting power in the ribs without loss of rigidity in the cartilages. These conditions of thorax are common in the subjects of tuberculosis.

The flattening of the thorax is increased by all impediments to the free passage of air through the air-tubes. In some children suffering from even slight bronchial catarrh, the flattening of the chest is seen to be increased at each inspiration; and if the impediment to the entrance of the air to the pulmonary tissue be constant or extreme, not only is the flattening increased at each inspiration, but the sternum is also depressed, especially at its lower half, below the level of the costal cartilages, and thus the antero-posterior diameter of the thorax is still further diminished in the median line.

b. Increase in the antero-posterior diameter of the thorax.—In rickets the cartilages of the ribs are very firm, while the adjoining growing ends of the ribs are softer than natural. The consequence of the extreme softness of the ribs at this part is that at each inspiration the weight of the atmosphere presses inwards the softest part of the ribs, while the sternum is borne forwards by the firm cartilages. The result is great increase in the antero-posterior diameter of the thorax, and diminution of the lateral diameter at the parts corresponding to the softest part of the ribs. The depression of the softest part of each rib is increased by the want of resilience of the softened structures.

A groove is thus formed in the thoracic walls just outside the ends of the costal cartilages; and this groove being deepened at each inspiration, the part of the lung adjacent is compressed in place of being expanded during the inspiratory act. At the same time, in consequence of the cartilages and sternum being thrust forward at each inspiration, air enters with undue force into the lung-tissue subjacent to these parts. The consequence of the excessive expansion of the anterior part of the lung is vesicular emphysema, and the recession during inspiration of the softened and imperfectly resilient and therefore deeply grooved part of the chest-wall leads to collapse of the subjacent pulmonary tissue; and, as the effect of these two conditions, the lungs, when the chest is opened, present a vertical groove corresponding to the groove in the chest-walls. The antero-posterior diameter of the thorax in rickets is still further increased by the curvature of the spine. The muscles are weak, the child is unable to sit upright, that is to say, it is unable, in consequence of the weakness of its muscles, to support the weight of the upper part of its body; the bones of the spine are, in common with the other bones of the body, softened; and the result of the weakness of the muscles and the softness of the vertebræ is the dorsal bow.

When deformity of the chest is the result of undue softness of the chest-walls, the position of the solid organs subjacent to the parietes is frequently perceptible to the eye. The liver supports the lower ribs on the right side, the heart supports the ribs and cartilages over it on the left side, and thus these organs cause local prominence of the chest-walls, without being themselves in any way abnormal.

In the so-called *pigeon-breast*, the antero-posterior diameter of the thorax is increased in the middle line, the lungs are small, the ribs and cartilages are firm, the ribs are placed obliquely and the chest-walls are flattened laterally, and the sternum as a consequence is thrust forwards; thus a horizontal section through a pigeon-breasted chest has a triangular form, the apex of the triangle being the sternum. Impediment to the free entrance of air into the lower lobes of the lungs will favour the production of and increase the deformity. The chests of children who suffer from repeated attacks of bronchitis may exhibit this deformity, while there is increased expansion and subsequent enlargement of the upper part of the chest, the lungs being more or less collapsed below and emphysematous above.

c. Transverse anterior constriction of the lower part of the thorax is the consequence of small size of the lungs, or of imperfect inspiratory expansion, permanent or frequently recurring in youth. In these cases the lower ribs are little used in respiration, while below they are borne outwards or supported by the liver, stomach, and spleen, and thus an imperfectly formed transverse depression is produced in the front of the chest on a level with the base of the ensiform cartilage (*Harrison's sulcus*).

II. Local, Asymmetrical, and Unilateral Deformities. — 1. *Fulness of the supraclavicular region.*—The supraclavicular region, corresponding to the portion of the thoracic cavity above the clavicle, may be fuller than natural. The causes of this local bulging are—*a.* Development of adipose and cellular tissue as in myxœdema. *b.* Distension of the deep-seated veins. *c.* Enlargement of lymphatic glands in a stout person. *d.* Large-lunged emphysema, in which disease there is occasionally distension of that part of the cavity of the thorax which lies above the level of the clavicle due to pressure within the lungs during the powerful expiratory effort of cough.

2. Depression of one supraclavicular fossa is caused by any pathological condition of the apex of the lung which produces diminution of its bulk, for example, atrophic emphysema, or chronic consolidation of the apex.

3. Elevation of one shoulder.—Occupation is a common cause of elevation of one shoulder; thus in clerks, who sit much at the desk, the left shoulder is permanently a little higher than the right, and the upper portion of the spine is slightly curved, the convexity being to the left; so in those who carry heavy weights on one arm, the opposite shoulder is elevated and the spine curved. Whatever necessitates an increase in the capacity of one side of the thorax causes elevation of the shoulder on the same side; thus, considerable dilatation of the heart, fluid in the pericardium, fluid in the pleura, aneurysm of the arch of the aorta or of the innominate artery, all lead to elevation of the shoulder. The shoulder is depressed and carried forward when, from any cause, the whole or upper part of one side of the chest is diminished in size, as when the apex of the lung is the seat of fibrosis in chronic tuberculosis.

4. *Uniform dilatation of one side* of the thorax is due, with one exception, to fluid or air in the pleura. The exception is those rare cases of malignant tumour of the lung, in which the new-growth is uniformly diffused through the lung-tissue, and in amount so great that the affected lung decidedly exceeds in bulk the healthy lung inflated with air by inspiration.

In uniform dilatation of one side of the thorax, the shoulder is raised, the ribs are placed more horizontally than on the healthy side, the intercostal spaces are widened, and the spine is slightly curved. When the enlargement is moderate in amount, the increase in capacity is effected by the altered position of the ribs; but when the increase in size is very considerable, then it is due in part to the pressure exercised by the air, fluid, or cancer-loaded lung on the inner side of the chest-wall.

5. *Uniform contraction of one side* of the thorax is the consequence of any condition which leads to general and uniform reduction in the size of the lung, such as cancer of the lung, chronic tuberculosis of the lung, chronic pneumonia, or the change in the texture of the lung which follows long-continued compression by fluid in the pleura. When the whole of one side of the thorax is reduced in size, the shoulder on that side is depressed, the ribs are placed more obliquely and are more closely approximated than on the opposite side, the intercostal spaces are narrowed, and the spine is curved, often considerably, the concavity of the curve being towards the contracted side.

6. *Lateral curvature of the spine*, instead of being the consequence, may be the cause of deformity of the thorax: the ribs are then approximated on the side and at the part where the concavity of the curvature is placed, while they are separated and the shoulder is raised on the side of the convexity.

7. In *angular curvature of the spine* the deformity of the thorax varies with the seat and the extent of the vertebral disease; but, speaking generally, it may be said that in angular curvature of the spine, while the capacity of the chest is much diminished, the antero-posterior diameter of the thorax is increased in proportion to the amount of destruction of the bodies of the vertebrae, and that the ribs are in a corresponding degree approximated.

8. *Extreme depression of the lower part of the sternum* is the consequence of softness of the cartilages of the ribs, and impediment to the free passage of the air to the pulmonary tissue. This deformity is never congenital, although the subjects of it often affirm it to be so; it may, however, commence to be formed directly after birth if there be a congenital impediment to the entrance of air into the lungs—for example, atelectasis. Later on, it may result from other impediments, especially if two or more co-exist—for example, post-nasal adenoids, enlarged tonsils, and chronic bronchitis.

This deformity may be the result of direct pressure. In certain occupations pressure has to be exerted on the lower part of the sternum—thus, some shoemakers use a wooden instrument which has to be kept in its place by pressure against the lower part of the sternum. For direct pressure to produce this deformity it must have been applied in early youth, while the parts are still flexible, and have been exerted frequently over a long period of time.

9. *Congenital deformities* of the thorax are few in number and are due to arrest of development—for

example, cleft sternum, and defective formation of one or more ribs or cartilages. See MONSTROSITIES and MALFORMATIONS.

10. *Asymmetrical diminution in size of a part* of the thorax is produced by any pathological change which reduces the size of the subjacent part of the lung. Chronic tuberculosis in the apex of the lung is attended by diminution of the bulk of the part of the lung which is the seat of the lesion. Considerable loss of pulmonary tissue is usually accompanied by falling inwards of the chest-wall over the cavity. The formation of a cavity is often attended by some fibrosis, and this increases the local depression of the chest-wall. In chronic thickening of the pleura, the chest-wall at the part is, by the contraction of the new fibrous tissue, drawn inwards, and the lung subjacent to the thickened pleura being often involved in the same process, the chest-wall is also forced in during inspiration by atmospheric pressure. Hence, after pleurisy, limited in extent, it is common to find permanent flattening of the thoracic parietes at the base of the chest on the side affected.

In cancerous infiltration of the lung, limited in extent, the lung-tissue is sometimes so much condensed that the bulk of the cancer and lung is less than that of the healthy lung, and the chest-walls as a consequence are flattened over the seat of disease.

11. *Asymmetrical localised bulging*.—If the ribs are, in relation to the size of the lungs, disproportionately long, and their cartilages soft, then one or more of the cartilages may be knuckled forwards; the cartilage, being compressed between the end of the rib and the sternum, bends in an angle outwards. Although the prominence is trifling, it often causes anxiety to parents and its subject. Local deformity of this kind is occasionally the result of repeated lateral compression of the chest-wall in the athletic sports of young boys, such as cricket.

All the diseases of the chest which are accompanied by general enlargement of both or one side of the chest, when localised, are attended by local bulging; thus, a common cause of abnormal fullness of the lower part of the left side of the thorax, posteriorly, is emphysema of the corresponding part of the lung; and a moderate amount of fluid in the pleura is attended by fullness of the lower part of the chest on the same side. In both these cases the ribs are raised into an abnormally horizontal position; the chest-walls are not pushed outwards, but the ribs are raised, and the intercostal spaces are to that extent widened. The ribs are put into the position which gives the greatest capacity to the thoracic cavities containing the fluid or the enlarged lung. Local bulging may be produced by aneurysm of the arch of the aorta or of the innominate artery; by growths, malignant or other, within the chest; by chronic pleurisy with effusion circumscribed by dense false membrane; by hydatids; or by abscess; and in all these cases the prominence is due to direct pressure on the inner side of the chest-wall, and to changes in the chest-wall itself.

Hypertrophy and dilatation of the heart and fluid in the pericardium are attended by fullness of the præcordial region. The bulging from these diseases is much greater in the child than in the adult. In these cases a little of the fullness is produced by a more horizontal arrangement of the ribs; but when the prominence of the præcordial region is at all considerable, it is the result of the pressure exercised by the fluid or by the large and powerfully acting

heart on the inner surface of the corresponding part of the chest-wall.

At the part corresponding to the junction of the first and second bones of the sternum, opposite the cartilage of the second rib, the sternum projects forwards. This prominence is called the angle of Ludovicus. Any impediment to the free entrance of air into the lungs may cause depression of the lower part of the sternum; if the ossification of the sternum is not complete at the junction of the first and second bones, undue prominence of this part is the result. Subsequently a formation of bone takes place at this spot, and increases the prominence.

CHEST-WALLS, Deformities of.—See CHEST, DEFORMITIES OF.

CHEST-WALLS, Morbid Conditions of.—

The walls of the chest may be the seat of various morbid conditions, and the affections of this portion of the framework of the body demand more attention than they are accustomed to receive. All that can be done within the limits of this article is to indicate their nature; to notice briefly such of them as are not described in other parts of this volume; and to point out the principles of treatment. They may be practically considered according to the following arrangement:—

1. **Superficial Affections.**—Under this group are included morbid conditions of the skin and subcutaneous structures. (a) Cutaneous eruptions are of common occurrence over the chest. Among these may be specially mentioned the eruptions of some of the exanthemata, herpes zoster, and chloasma. (b) The superficial vessels are liable to become enlarged under certain circumstances. This enlargement is usually seen in the veins over the front of the thorax, which may be distended on both sides, or only on one side, or in some particular region. The larger divisions may alone be involved; or a more or less extensive network of smaller veins is visible, and occasionally even the capillaries seem to be implicated. This condition generally arises from some obstruction interfering with the circulation through one or other of the principal veins which, either directly or indirectly, receive the blood from the veins of the thoracic wall. Thus the superior vena cava, or either innominate, subclavian, or axillary veins may be implicated, being, for example, pressed upon by new-growths or enlarged glands, the distribution and extent of the venous distension varying accordingly. Occasionally one of the smaller veins is thus interfered with. The writer has met with cases in which considerable enlargement of the veins was visible over portions of the thorax, where the cause was by no means evident, the patients asserting that this condition had existed ever since they could remember, and being regarded by them as perfectly normal. Probably it has resulted from some local obstruction occurring during early life. It must be remembered that women who are suckling frequently present considerable enlargement of the superficial veins over the front of the chest, which usually subsides when the period of lactation is at an end, but may become permanent after several children

have been nursed. Again, more or less venous and capillary engorgement in this region may occasionally be observed in cases of cardiac or pulmonary disease. Sometimes a ring of enlarged veins and capillaries is seen round the lower part of the chest. When the venous distension is due to obstruction of the superior vena cava, the skin presents a more or less marked cyanotic tint; and in cases of general cyanosis, the chest, in common with other parts, may have a cyanotic appearance. Occasionally one or other of the small arteries which supply the thoracic walls is enlarged, and it may attain a considerable size. (c) Subcutaneous œdema is sometimes observed over the chest. In most instances this is a local condition, being the result of venous obstruction; but it may be a part of general dropsy, particularly in connection with renal disease. This morbid state is evident on inspection and palpation, and the affected part pits on pressure. (d) The thorax is one of the most common seats of subcutaneous emphysema, in which gas, consisting usually of air which has escaped from the respiratory apparatus, collects in the cellular tissue, and travels, to a greater or less extent, over the body. The causes of this condition are described elsewhere (see EMPHYSEMA, SUBCUTANEOUS). Subcutaneous emphysema is attended with evident swelling of the part, which usually develops rapidly, and may be very great, all the normal anatomical outlines being obliterated. It has an elastic feel, and pits readily on pressure with the finger, but speedily rises again; the peculiar minutely crepitant sensation accompanying this condition is elicited on palpation and percussion; percussion yields a curious, superficial, muffled, tympanitic sound; and on auscultation a superficial small, dry, crepitant sound is heard. (e) As belonging to the superficial affections of the chest may be just mentioned diseases of the mammary gland or nipple, which of course constitute a most important class of diseases in females. See BREAST; and NIPPLE.

2. **Muscular and Tendinous Affections.**—

(a) The muscles of the chest or their tendinous attachments may be the seat of certain painful affections. These are of the nature of so-called muscular rheumatism or myalgia, of inflammation, or of more or less injury or strain. They are induced by cold, constitutional conditions such as gout, overwork, straining, violent coughing, fatigue from prolonged sitting, and other causes. The painful condition is usually localised, but different muscles are involved in different cases, sometimes those which are superficial being affected, in others the deeper muscles, including the intercostal; or the complaint may be confined to a single muscle. Pleurodynia, dorsodynina, and scapulodynina are the terms applied to muscular rheumatism affecting the side of the chest, the upper part of the back, and the scapular regions respectively. As the result of severe coughing, muscular pains are very common around the lower part of the chest. The pain is usually more or less aching in character, and not severe, but it may be very intense, especially in acute cases. Whatever brings the affected muscles into play aggravates the suffering, such as moving the arms or shoulders when the superficial muscles are affected, coughing, sneezing, and similar actions. In some instances the pain is not felt when the affected structures are kept quite at rest. There may be local tenderness on pressure, or

diffused pressure may give relief; while posture often influences the sensations experienced, such as whether the patient assumes the recumbent or sitting posture, or lies on one or other side. Fatigue generally increases the pain. Muscular affections connected with the chest are not necessarily accompanied with any other local symptoms; and physical examination reveals nothing, except that perhaps the act of breathing is voluntarily restrained, on account of the pain thus induced. (b) The muscles of the chest may be affected, on the one hand, with spasm or cramp; on the other, with paralysis. The former is attended with more or less pain, usually localised, which may be very severe; the latter is indicated by loss of power in the muscles involved. These disorders generally depend on some lesion of the central nervous system, but may result from local nerve-disease. Muscular cramp may arise from a sudden twist of the body, and it is usually supposed to be the cause of the 'stitch' in the side brought on by running, but this is doubtful. In cases of hemiplegia from cerebral mischief, the muscles of the thorax on the affected side are often temporarily weakened, but they usually subsequently soon regain their power. When the upper part of the spinal cord is injured or diseased, all the muscles of the chest become paralysed. (c) Atrophy or degeneration may involve more or less of the thoracic muscles. In cases of pulmonary phthisis either the whole of these muscles or certain of them are not uncommonly wasted out of proportion to the general emaciation. They may also be implicated in progressive muscular atrophy; and occasionally a single muscle undergoes marked wasting. The writer has seen a striking example of this local atrophy in connection with the pectoralis major, but the serratus magnus or other muscles may be implicated. The wasting is probably in most cases due to disease of the nerves supplying the affected muscles. It is quite evident on examination, and the movements which are usually performed by the involved structures cannot be executed properly. (d) On the other hand, the chest-muscles may become hypertrophied. This may be a natural result of athletic exercises and training; or it may occur in consequence of their being called upon, either habitually or at intervals, to act excessively, as in cases of emphysema or asthma. In exceptional instances the condition known as pseudo-hypertrophic muscular paralysis has extended up to the chest. (e) The thoracic muscles not uncommonly present marked irritability under percussion or friction. This has been regarded as an important sign of phthisis; but the writer has often found it equally if not more evident in cases where the lungs were perfectly healthy. (f) As the result of injury and other causes, some portion of the muscular structures of the chest may be lacerated, ruptured, or perforated, either alone or along with other structures. This condition will be further alluded to presently.

3. Nervous Affections.—(a) Neuralgia is very common in different parts of the chest, especially in the side, and particularly the left side—*intercostal neuralgia*. The pain is localised, being usually referred to a point where a branch of nerve becomes superficial. It is more or less constant, in some cases being at times very severe. It often precedes or follows an eruption of herpes. It may be increased by deep breathing or coughing, but is not as a rule so much affected by these and similar

actions as are other painful chest-affections. Shooting and darting sensations often radiate from the principal point, and certain spots of tenderness—*points douloureux*—may be recognised (see *INTERCOSTAL NEURALGIA*). (b) Intercostal neuritis is occasionally met with, and this affection is attended with great pain, localised and radiating, with much tenderness, the suffering being aggravated by whatever causes any local disturbance. It is probable that the severe pains experienced in some instances where the complaint is supposed to be muscular, are due to branches of nerves being inflamed. Severe pain often precedes or follows herpes zoster, and this probably depends upon actual nerve-changes. It may also be mentioned here that pains around the sides may be associated with disease of the spine or of the spinal cord. (c) Some individuals, especially females, exhibit a remarkable superficial tenderness or hyperæsthesia over the thorax or in parts of this region, especially the anterior and upper portions. The slightest touch is resented, and the most delicate percussion cannot be borne. This condition may exist without any actual disease, or it is sometimes observed in phthisical cases. (d) Sensation may be more or less impaired over the chest, or in limited portions, either in connection with central or local nervous disease, or in hysterical and neurotic persons. Various paræsthesiæ are also frequently referred to this region by the class of individuals just mentioned.

4. Diseases of the Bones or Cartilages.—

The morbid conditions which may be referred to the bony and cartilaginous framework of the thorax are as follows: (a) The chest-walls are often unduly rigid and firm, owing to an excessive deposit of calcareous matter in the sternum and ribs, with ossification or petrification of the cartilages. This is a normal condition in old people, being one of the degenerative changes to which they are liable, but it also occurs not uncommonly in younger individuals, as the result of hard work, or excessive athletic exercises, or in connection with certain pulmonary diseases. This state of rigidity interferes more or less with the respiratory movements, and not infrequently causes serious embarrassment. (b) On the other hand, the ribs and cartilages may be deficient in firmness, and consequently too yielding and elastic (see *CHEST, Deformities of*). (c) Acute or chronic periostitis or perichondritis is sometimes observed in connection, respectively, with the sternum or ribs, or with the cartilages. The acute affection gives rise to limited pain and tenderness, which may be accompanied with superficial redness and swelling, and may simulate some more serious disease. The chronic complaint usually assumes the form of a node, being the result of syphilis. The writer has occasionally observed a small swelling at the junction of one of the ribs with its cartilage, painless, unaccompanied with redness, but with fluctuation. (d) The bony and cartilaginous structures themselves may be the seat of disease in some part of the chest, and here must be included the portion of the spinal column which limits this region posteriorly. Thus there may be acute inflammation, caries, or necrosis. Among the more important causes which may originate these conditions are injury, syphilis, tuberculosis, empyema opening externally, and thoracic tumours or aneurysms growing outwards. They may lead to serious consequences, both local and general, and frequently cause

more or less deformity of the chest. (e) Permanent thickening and distortion of portions of the ribs occur after fractures which have united improperly.

5. Inflammation and Abscess.—It is expedient to make a separate group of those cases in which inflammation, resulting in the formation of one or more abscesses, occurs in some portion of the soft structures entering into the construction of the chest-walls. This may be of local origin, arising from injury, bone-disease, or other causes; or it may be due to the opening of an empyema into the tissues; to suppuration extending and burrowing from the axilla or other parts; or to pyæmia. If deep-seated, an abscess may be difficult to detect with certainty, but usually the signs of this condition become sufficiently obvious. Sinuses or fistule may be left as a consequence of suppuration in the chest-wall, especially when pus makes its way outwards from within.

6. Tumours and New-growths.—These morbid conditions also demand brief notice. They may be connected with any of the structures of the chest-walls, and are of various kinds; among those which have come under the writer's notice may be mentioned fibromata, fatty growths, cystic tumours, enlarged sebaceous glands, and infiltrated carcinoma. Tumours may make their way inwards from the chest-walls, encroaching upon the cavity of the thorax; or, on the other hand, the walls may be involved by growths extending from within. It need scarcely be mentioned that mammary tumours constitute a distinct and by far the most important group associated with the structures covering the chest. See BREAST, Diseases of.

7. Perforations and Ruptures.—The muscular structures of the thoracic wall may be more or less destroyed in some part, either by sudden rupture or gradually, allowing a hernial protrusion of the lung to take place between the ribs. As already noticed, empyema may make its way externally through the chest-wall. Aneurysms and tumours extending outwards from within the thorax frequently cause serious destruction of the tissues, including the bony and cartilaginous as well as the soft structures. This destructive process is often attended with severe pain and suffering, and leads to grave mischief. Congenital clefts or more extensive deficiencies are sometimes met with in the sternum or other parts of the thoracic walls.

8. Variations in Form and Size.—The chest often presents deviations from the normal shape and size, and these are so important that they demand special consideration. See CHEST, Deformities of.

TREATMENT.—In many cases where the chest-walls are in a morbid state, either they do not need any special treatment, or no treatment can be of any avail. The chief circumstances under which the practitioner may be called upon to interfere, and the measures to be adopted, may be briefly indicated as follows:—

(a) Painful affections of the chest-walls, depending upon conditions of the muscles or nerves, frequently demand local applications for their relief. Thus in different cases it may be requisite to employ hot fomentations, dry heat, or cold applications, in the form of wet rags frequently changed, ice, or evaporating lotions; or to use anodyne applications of various kinds, such as belladonna plaster or liniment, opium plaster or liniment, oleate of morphine, tincture or liniment of aconite,

or ointment of aconitine or of veratrine. Anodynes may also sometimes be added to fomentations with advantage. Friction is often of much service, and at the same time stimulating liniments may be employed, such as one containing camphor, chloroform, or turpentine. For ill-defined muscular pains about the chest, which are frequently complained of, free douching with cold water every morning, followed by friction with a rough towel, is often highly efficacious. When pain is localised and obstinate, much benefit may in many cases be derived from the application of a sinapism, mustard-leaf, or even a small blister. In other instances the use of the ether-spray is serviceable, repeated more or less frequently; or sometimes much relief may be obtained from applying over a painful spot a mixture of equal parts of chloroform and belladonna liniment. Galvanism is another agent which may be of the greatest service in relieving painful sensations about the chest, whether connected with the muscles or nerves. Subcutaneous injections of hot water, morphine, or atropine may be demanded in some cases, and constitute a most valuable mode of treatment if pain cannot otherwise be assuaged.

In the treatment of many painful affections of the chest-walls much assistance may be derived from attention to posture, especially in connection with certain occupations; from the avoidance of undue fatigue, or of any violent actions which are known to influence this part, such as cough; and from the adoption of measures tending to support the structures, or to keep them in a state of rest. The writer has found great benefit in a large number of instances from strapping the side more or less extensively, in the manner advocated by him for the treatment of pleurisy; and if there is any localised pain, some limited anodyne application, such as a piece of belladonna plaster, may be placed over this spot under the strapping.

(b) In many affections of the chest-walls, treatment directed to the general system, or to some special constitutional condition, is often of the greatest service. Thus, in the painful complaints already noticed, there are frequently marked general debility and anæmia; and essential benefit is derived from the administration of quinine, preparations of iron, strychnine, cod-liver oil, preparations of phosphorus, and other tonics. Some of these are also useful when there is disease of bone and its consequences. Again, certain affections of the thoracic wall may be associated with rheumatism, gout, or syphilis, and then the particular treatment indicated for these several diseases is called for.

(c) When disorders of the muscles of the chest-walls occur, such as paralysis or spasm, associated with some disease of the central nervous system, the treatment must usually be directed to this disease, and but little can be done for the local disturbance. In some instances, however, electrical or other modes of treatment may be of some service, by influencing the action of the muscles, but no definite rules can be laid down.

(d) Local inflammation and its results in connection with the thoracic walls must be treated as in other parts of the body, but it is unnecessary to discuss this subject in the present article.

(e) Surgical treatment may be called for under certain circumstances. Of course this will be the case if the chest-walls are injured in any way. Among other conditions likely to demand surgical interference may be specially mentioned sub-

cutaneous emphysema, abscesses, disease of the bones, and tumours.

FREDERICK T. ROBERTS.

CHEYNE-STOKES RESPIRATION.—A peculiar disturbance of breathing, first described by the late Drs. Cheyne and Stokes, of Dublin. See *RESPIRATION, Disorders of*.

CHICKEN-POX.—**SYNON.** : *Varicella* ; Fr. *La Varicelle* ; Ger. *Wasserpocken*.

DEFINITION.—An acute specific infectious disease, characterised by the appearance, in successive crops, of red spots, which in the course of about a week pass through the stages of pimple, vesicle, and scab.

ÆTIOLOGY.—It is certain that this disorder arises from contagion, but the specific organism has not yet been isolated. It may be met with at almost any age, but is most common in young children.

SYMPTOMS.—The illness commences without any, or with but slightly marked, premonitory symptoms. There is usually some headache or feeling of lassitude. Within a few hours an eruption appears, generally on some part of the back or chest, but there are many exceptions to this rule. It may commence on the face, neck, chest, abdomen, or extremities, or upon several of these parts at the same time ; the scalp is almost invariably invaded. The eruption consists of small, faintly papular rose-spots, varying in number from a few to a hundred or more. These, in the course of eight, twelve, or, at the most, twenty-four hours from their appearance, change into vesicles, which, at first small in size and clear as to their contents, become quickly large ; globular, or semi-ovoid, in form ; translucent, glistening, and opalescent in appearance ; and surrounded with a faint areola. Towards the end of the second day the vesicles attain complete development, and about this time a few may be seen on the sides of the tongue, on the mucous membrane of the lips, cheek, or palate, and sometimes upon that of the genitals. About the third day a few of the vesicles may have a pustular appearance, and sometimes a few pustules are seen ; but regarding the eruption as a whole, pustulation forms an incident rather than an essential feature in its progress. On the fourth day the vesicles begin to dry up, and by the sixth complete scabs are formed. These fall off in a few days, leaving in their place faintly red spots, and sometimes a few pits. A single crop of eruption may be said to complete itself in five or six days ; and, as two or three crops appear on as many successive days, the illness will last rather more than a week. In the event, however, of there being a succession of crops, it may be prolonged for another week, but this is unusual. With the appearance of the eruption, the temperature may rise two, three, or even more degrees, and this may recur with each successive crop of spots, but in many cases there is no rise of temperature at all. The pulse is sometimes slightly increased in frequency ; the tongue is moist, and sometimes covered with a slight fur. As a rule, however, there is but little constitutional disturbance, although it is occasionally severe.

PATHOLOGY.—Chicken-pox is due to the reception of a specific poison, which, after an incubation of not less than thirteen or more than twenty days, shows itself by an eruption upon the skin. It affects the same individual once only. The infection

may be conveyed as soon as the eruption has appeared, if not before, and a patient may be regarded as free from infection, and therefore fit to go home or rejoin school, when every scab has fallen off, particular attention being paid to the scalp. Chicken-pox is not one of the diseases to which the *Infectious Diseases Act* (1889) applies.

COURSE AND TERMINATION.—Chicken-pox almost invariably runs a favourable course ; in tubercular children occasionally the vesicles instead of drying up in the usual way go on to the formation of ulcers and the child dies of exhaustion ; this form has been called *varicella gangranosa*. In rare instances grave lesions of the central nervous system have followed an attack of chicken-pox.

DIAGNOSIS.—In the earliest stage there may be a difficulty in distinguishing between chicken-pox and a mild attack of modified small-pox, but in the latter there should be the premonitory symptoms of illness, and especially the pain in the back. Moreover, the rash is at first ‘shotty,’ which it never is in chicken-pox. The vesicles in small-pox should always have a central depression ; in chicken-pox this is absent, the vesicles rapidly becoming scabbed. The fever subsides when the eruption appears in small-pox, the reverse being the case in chicken-pox.

TREATMENT.—The patient should be confined to his room, perhaps in the more marked cases to his bed, and isolated from those who have not had the disorder. No special treatment is called for, and complete recovery is the almost invariable result.

JOHN ABERCROMBIE.

CHIGOE.—The chigoe or jigger is a minute parasitic insect belonging to the genus *Pulex* and known as the *Pulex penetrans* or sandflea. It is common in the West Indies, tropical America, and tropical Africa.

The chigoe resembles the ordinary flea, but the head is proportionately larger and the abdomen deeper. It lives in dry and sandy soil, especially when this is mixed with animal refuse. It attacks any warm-blooded animal. After impregnation the female buries herself beneath the skin, the two posterior segments of her abdomen plugging the aperture through which she had entered. The feet, especially between the toes and at the root of the nails, are favourite sites ; but any part of the body may be attacked, and any number of jiggers, from one to one hundred or more, may be present in a single patient. The abdomen of the parasite swells during gestation to the size of a pea, the enlargement being accompanied by suppuration and necrosis of the skin round the aperture, leading to the formation of a small ulcer from which the parasite is finally expelled. The ulcers may become infected with the organisms of tetanus, phagedæna, or other diseases, and serious and even fatal results ensue. In the meantime the ova, being expelled, fall on the ground and pass, in the usual way, through the larval and cocoon-stages until the fully formed parasite is finally developed in less than a fortnight after the expulsion of the ova.

TREATMENT.—This should be in the first place prophylactic. Wherever the parasite is known to exist, the ground-floors of all houses and out-houses should be carefully cleansed. Shoes should be worn invariably. The frequent application of carbolic acid, and other antiseptic lotions, to the feet is said to offer some protection against the parasite. Any irritation in the foot should be at once attended

to, and any chigoe that can be found on, or in, the skin should be at once removed, in the latter case by enlarging the opening and extracting the parasite with a needle.

PATRICK MANSON.

CHILBLAIN. — SYNON. : *Erythema Pernio* ; *Pernio* ; Fr. *Engelure* ; Ger. *Frostbeule*.

DEFINITION.—A form of dermatitis induced by cold.

ÆTIOLOGY.—Chilblains are commonest in children and young persons. They are most prevalent in winter, and are more frequent in girls than boys, doubtless owing to the greater susceptibility of the vaso-motor system, but they indicate more than a defective circulation. They may be considered as an indication of debility and deficient vital power. Their occurrence is influenced more by the strength of the individual than by the degree of cold, and they continue in some persons throughout the entire year. Their tendency is to cease with the full development of the system : they occasionally reappear in advanced life.

DESCRIPTION.—The regions of the body usually affected with chilblains are the toes, outer margin of the little toe, edge and dorsum of fingers, the chin, nose, ears, and heel (hence the term ‘pernio,’ from *πέρνα*, the heel). A chilblain presents three stages or degrees of severity, namely, *erythematous*, *vesicular*, and *ulcerated* ; and it may be arrested at the first or second stage by the withdrawal of the cause. The *erythematous* stage is restricted to dusky redness, swelling, and burning and intolerable itching, the itching being increased by heat, as by sitting in front of the fire, or by active exercise. The congested spot is circular in figure, somewhat tumid, brightly red at first, but later on roseate crimson, purple, or livid in colour. The ‘local asphyxial stage,’ which constitutes the mildest form of Raynaud’s disease, is a somewhat similar pathological condition (see RAYNAUD’S DISEASE). The second stage exhibits the blister resulting from effusion of serum beneath the cuticle ; the permanent colour of the swelling is now purple or livid ; and the contents of the blister a limpid serum. In the third stage the blister is broken, and a small ulcer results, which is often difficult to heal—this constitutes the ‘broken-chilblain.’

Cold first causes vaso-constriction of the arterioles followed by dilatation from vaso-motor paralysis ; and then follow the other inflammatory phases. See CIRCULATION, Disorders of.

Erythema pernio has to be diagnosed from an early stage of lupus erythematosus ; occasionally the two affections are co-existent. See LUPUS ERYTHEMATOSUS.

TREATMENT.—The principles of treatment of chilblains require to be modified to suit the different degrees. Prophylactic treatment is the best. This implies keeping the extremities warm, wearing thick solid loose-fitting boots, wash-leather socks, double-lined gloves, velvet bracelets ; daily systematic out-of-door active exercise (running, walking, cycling, skipping). In the first stage, the indication is to restore normal circulation by gentle friction : then some soothing liniment may be employed ; and, finally, a stimulating liniment, covering the part afterwards with ointment of menthol and lanolin and cotton-wool, or shielding it with lead or opium plaster spread on wash-leather. The applications most in favour for this purpose are the

soap liniment with chloroform and laudanum, the compound camphor liniment, the turpentine liniment, the tincture of iodine, and Goulard’s Extract. In the vesicular stage a similar treatment may be used to the erythematous portions, while the blister should be snipped and the broken surface pencilled with the compound tincture of benzoin, and afterwards dressed with unguentum resinae or an ointment of Peruvian balsam. In the third stage the erythematous phenomena still require attention, and the ulcer should be dressed with unguentum resinae, either alone, or in combination with antiseptics.

To obviate constitutional debility, the diet should be nutritious and generous, and recourse may be had to nerve tonic remedies, such as liquor arsenicalis and the best hygienic surroundings. See FROSTBITES ; COLD, Effects of Severe and Extreme ; RUBEFACIENTS.

JOHN HAROLD.

CHILDREN, Backward. — See CHILDREN, Training of.

CHILDREN, Clinical Examination of. — See INFANTS, Diseases of.

CHILDREN, Training of. — Training may be begun before the use of words, and a proper understanding of them, are acquired.

The general characters of brain-action observed in an infant or young child—regard being had to its age—indicate its potential mental capacities. These signs vary at different stages of evolution. The final result much depends upon continuous growth and healthiness ; hence these characters should be watched and duly cultivated. Spontaneity of action in the nerve-centres is indicated in childhood by general mobility ; this forms the basis of future mental power. While the infant is awake spontaneous movements are seen in the limbs, especially in the small parts ; the fingers and toes move individually or collectively, but without uniformity and in no apparent order. These movements are slower than those of adults ; they are almost constant except in sleep, and are but little under the control of sensory impressions. This spontaneous movement of infancy the writer has described under the term *Microkinesis*. Gradually in the advancing months of early life the centres begin to act in combinations, co-ordinated to some extent by sight and sounds. At about the fourth or fifth month the sight of an object may temporarily inhibit the movements, and this may be followed by turning of the head, eyes, and hands towards the object seen, i.e. the co-ordinated action is consequent on a period of inhibition following stimulation. From such observations we infer that at birth the nerve-centres act slowly and independently of one another ; that, as evolution advances, their action may be temporarily suspended by sensory stimulation ; and that, during the time when no efficient nerve-currents are passing to produce visible movements, the centres undergo a physiological change—possibly due to action in their dendrons—subsequently indicated by new and co-ordinated movements. Such observations show the existence of an initial faculty of ‘mental attention.’ The imbecile infant does not exhibit this microkinesis in a normal degree ; its nerve-centres are wanting in spontaneity, and, later on, in the capacity for co-ordination.

The object of early training is to bring the spontaneous activity of the nerve-centres under control, so that they may subsequently act in harmony with the child's environment, and that the evolution of the brain may be guided in such a way as to fit it for the work of mental life. In the Infant-class, bright faces, ever moving hands and fingers, with readiness for chatter or response, show spontaneity of the brain-centres, free action, ready for the methodical training which may co-ordinate the brain but not suppress its activity.

The principal means of controlling the brain and producing impressions upon it are through the eye by sight and the ear by hearing; but besides these, stimuli may reach the brain through the other senses and from the muscles and other organs of the body.

Muscular sense as a means of training the brain has been too much neglected in educational methods. It is easily employed before the use of words is possible; while, further, the response to impressions thus produced can be *seen* by the teacher, and then the improvement in accuracy produced by repetition is observable. Muscular sense may produce effects in the brain in two ways, which, as they differ in methods of employment and their uses in training, may be classed separately, as—(1) Impressions by muscle-sense during contraction; (2) impressions produced by the muscles in tension or by the strain of weights or pressure. As examples of the former variety we know that impressions are produced by movements of the eyes or the hand, as in looking at or pointing to objects in succession, and in counting them, or in following the movements of a pendulum; also in measuring the length and size of objects with the fingers. Illustrative of the latter group we have the impressions produced by muscle-tension, as when feeling a weight in the hand, the strain felt being proportional to the weight used. These two kinds of impressions by muscular sense are here separated because in training they are employed differently, and lead to different modes of mental comparison and description; the size of objects may be compared, but must not be confused with their number and their weight any more than the characters of hardness and of colour. Each kind of impression should be produced separately in elementary training. The size of a coin can be seen by eye-movements or be felt in the hand with the fingers closed around it while the limb is supported, so that the weight shall not be felt; thus weights and sizes can be compared respectively.

Early training should be designed to develop control rather than to impart information. Training must proceed stage by stage; each method used needs to be often repeated to produce an effect, and to ensure accuracy and retentiveness. Each point in training should be planned to bear on future work, and no more difficult brain-process attempted till the elements of the action which it involves have been acquired. One of the earliest requirements is to control the child's eyes: this applies equally to the very young child, to the neglected and untrained pupil, and to those adults who are childish and dull in make of brain.

Let the teacher try to get the child to look at her face, or at a coin or bright object held in the hand and moved in different directions, following it as it moves. At first the child will do this by moving his head only without moving the eyes in his head. *Eye-drill* is very useful. Let the child look at

objects in the room, at a ball as it is thrown, or at a light flashed from a candle. At first, sight stimulates eye-movements; later he moves his eyes, directed by sound as he is told what to look at. Sight impresses the brain, so do eye-movements, and these produce impressions by muscular sense which are subsequently useful when the child is learning the meaning of numbers, as in counting, when the eyes are turned to one object after another.

In speaking of *hand-movements* reference will be made to training intended to educate the brain, and thus to lead to mental faculty, rather than to manipulative processes, games, or gymnastic exercises, all of which are none the less useful. Let the child imitate the action of his teacher, holding out one hand straight and free, on a level with the shoulder, the elbow straight and the fingers all in the same plane. Instinctively the child's left hand imitates the teacher's right hand. When slow movements are made in bending the fingers one or two at a time, these are imitated at first very inaccurately, but by frequent practice imitation becomes more exact according to the degree and the time of each finger-movement. The good training which is thus afforded exercises control; as each centre in the teacher's brain moves a finger, the corresponding centre in the child is brought into activity in similar degree and relations of time of action; further, the effect produced can be observed. Such exercises soon fatigue a young brain, and should not be continued for more than a minute at a time. It will be found that in succeeding lessons such series of movements become more regular, more exactly controlled by sight, and that a slighter stimulus produces the desired effect till the exercise is retained or remembered and can easily be reproduced without further guidance. We infer that during practice the brain-centres are being gradually prepared for action in harmony with one another, so that they become more capable of regulated or co-ordinated action. At first the nerve-centres are merely brought into action in certain groups; after repetition they seem to grow together, so as to tend to act in one union of cells. It may be that they become functionally connected through their dendrons. These impressions made on the cells are strengthened by repeated training, as an organisation is built up. Such previous training proves useful later on in the process of teaching the significance of numbers; the child feels that four movements of his arm are greater than two. Imitation is important in speech-teaching, which is needed by all children. *See DUMBNESS.*

Muscular sense in tension is also to be exercised. Let the child hold out his hands in front, supinated, with the fingers open; then place an ounce weight on the fingers so that the strain is felt as apart from dimensions or bulk. When subsequently it is required to distinguish weight from size, or to make comparisons as to size and weight respectively, the previous separate impressions received will be useful in giving an understanding of the subject taught. Let the child feel the strain of the weight on his hand, then feel the size with his fingers closed, while his arm is supported or rests on the table so that he does not feel the weight. For instance, in teaching the coins it is best to produce each class of impression separately: the feeling of weight and size respectively by muscular sense, then the colour by sight; let the child learn to pronounce the name of the coin, then look at it, and

finally name it at sight ; the previous training is used in describing what is seen. Accurate impressions received one at a time enable comparisons to be made, but the comparison must be of impressions of like kind : weight may be compared with weight, size or dimensions with those of like character, and colour may be matched at sight. In comparison and description impressions have to be classed ; therefore each kind should be implanted separately in early training. Another point is that one class of impression at a time is more easily received and retained in the brain and is less confusing and fatiguing. Speak to the child ; show him a colour, an object, or make him feel either its size or weight, but do not produce each kind of impression at once in the earliest methods of training. Proceeding thus stage by stage, the child is prepared for more advanced educational methods. Eye-movements well under control lead to accurate seeing and reading ; they are employed in counting objects and in adding figures on paper : the student who does not fix his eyes well becomes an inaccurate observer. Trained muscular sense leads to a ready appreciation of weight and dimensions, their comparison, proportions, and description ; impressions made separately upon the brain are retained, and become associated with one another and connected with ideas and the use of words in education.

Standards of weight, measurement, and time, as well as the use of numbers, must be taught. For this purpose impressions are produced one at a time by carefully placing in the open hand in turn weights of one, two, and three ounces—first produce the impression, then name the weight. A knowledge of length may be taught by making the child move his eyes in looking at horizontal and vertical lines on the blackboard, which should be vertical against the wall, the lines being divided into inches, but care must be taken that the eyes are moved in looking. Movements made with the finger one inch at a time also produce impressions of length. Impressions of the duration of time may be implanted by counting the movements of a seconds-pendulum, or by noting how long it takes to walk a hundred yards, or in other ways, giving ideas that can afterwards be used.

Discrimination or the appreciation of agreement and difference in objects may be cultivated by training, planned to produce at first a few impressions of each kind. A very young child can distinguish between the objects and colours presented, and will respond readily to certain sounds ; sorting out objects of like size, weight, or colour is an elementary preparation for making comparison, and precedes the faculty of judgment. Retention and discrimination of sensory impressions under guidance lead to experience, which forms the basis of intelligent choice. In training stage by stage, the pupil can be made to *feel* the greater strain of four ounces in his hand after the two-ounce weight ; he may then be taught that this is the 'greater weight,' 'twice the weight.' He *feels* the difference and then learns how to express this ; similarly he can be made to feel and then express which is the longer stick. The child must learn how to look at and examine objects, and be taught the means of comparing and describing what he sees and feels. All this requires much time and practice in observing things which are alike and unlike, noting in what characters the agreement or difference consists.

The teacher must carefully consider some one point for comparison—it may be weight, length, size, or colour ; each of these characters should have been taught previously by many examples.

In seeking a scientific basis for the art of training we must not be satisfied with a connected train of ideas in our own minds which may be implanted in the child's brain by the use of words only ; we should endeavour to trace out the impressions produced in good teaching which become associated in later teaching and experience. With pupils a little advanced in their mental training it may be useful to let them examine an object for themselves, say a bean or a flower ; they thus acquire many different kinds of impressions at the same time as they see, feel, and handle the object. They should gain impressions as to the number of parts, their form, size, colour, weight, &c. When however the child proceeds to make comparisons and give a description, he must separate and classify the different impressions received ; in this process guidance will be necessary till trained mental habits have been acquired. When sufficiently advanced in education, the pupil can be trained to observe and note the time of events, with the order in succession of their occurrence, as preparatory to studying Natural History and the Physical Sciences. Impressions produced by observation of facts in the order in which they were seen must be retained in the brain. Further training and practice will be needed to educate the child to see and understand that when peas are soaked in water they become increased in size and in weight, while a proportionate weight of water disappears from the vessel containing them. If the peas are placed on damp moss for a few days they will be seen to sprout, the root growing downwards, while the stem grows more slowly upwards. When light reaches the plant the young leaves become green, but not till *after* the light comes to them ; if grown in darkness they are not green. If the plant is kept in a room, as the stem grows longer it is bent towards the light. To follow the teaching given, the pupils must be previously practised in estimating length by sight, also size and volume, and must also be conversant with the comparison of lengths, sizes, weights, and the colours respectively, so as not to become confused in mental action and try to compare size and weight which may not be proportional. It requires much previous training to enable the child to see that the concave side of the stem of the plant is shorter than that which receives less light. Familiarity with the methods of noting and remembering the order of events will show that the presence of water precedes the swelling of the peas ; that the unequal illumination of the two sides of the stem precedes unequal bilateral growth, and that bending in the direction of the light results in consequence. In such methods of educational training we teach observation of antecedent and sequent events in place of speaking of cause and effect, or allowing verbal explanations expressed in terms *because, therefore*. The order of associated impressions and ideas received is important, and tends to be retained in the brain, while it is strengthened by repetition ; co-ordinate physical exercises help to cultivate this mental faculty. Associated impressions and their attendant thoughts when firmly retained revive in the same connection. The cultivation of character and voluntary power may be partly effected by the training here briefly

sketched, as well as by implanting thoughts and principles through the use of words.

Retention of the order in which the pupil has made his observations has much to do with his logical thinking and understanding antecedents and sequents or cause and effect; the order of the numerals together with the degree of the weights and lengths compared respectively, and expressed by use of the numerals, is necessary in mental estimation of the weight, bulk, mass of objects, and also to appreciation of the probable value of the quantities of material seen, as in the practice of 'school shop.'

Dull and backward children and those organically 'feeble-minded,' as well as all young children, need carefully planned training to help in evolving their mental faculties. Besides cultivation of the natural characters of brain-action, any phenomena indicating faults and defective conditions of the nerve-centres should be observed, and when possible replaced by better forms of activity. These faults are expressed in movement and postures seen in the body; the observation of these detailed neuromuscular signs and balance of the limbs and face will afford definite guidance as to the method and degree of training adapted to the individual child. Observation of the pupil should always accompany and direct training.

The *face* may be taken as an index of the brain. The expression of a child's face should be lively, changeful, mobile, showing spontaneity and response: not fixed, defective, or absent. Stimulus and proper occupation will often improve expression and also remove for the time some of the uniformly repeated nerve-signs to be described. The *frontal muscles* which produce horizontal creases on the forehead may be seen to move spasmodically and irregularly; these muscles are generally quiet when the child is interested, and may thus afford a guide to this condition of the mind. *Corrugation* or 'knitting' of the eyebrows is often associated with some form of mental stress, such as fright or hard mental effort. Observation of the conditions under which it subsides or increases may supply useful indications for management. *Frowning* is frequently associated with the presence of headache, and should suggest the possible existence of ocular defects (myopia, &c.). Spasmodic movements of the facial muscles may develop into habits which are often difficult to eradicate. *Fulness under the eyes*, due to relaxation in tone of the orbiculares oculorum, is an early sign of fatigue and common accompaniment of headache; if the child smiles or laughs it disappears for the moment. The fatigue may be temporary, as from mental work, insufficient feeding, a close atmosphere, or late hours. *Grimacing*, or over-smiling, with deepening of the nasolabial lines, is seen with low-class brains as a uniformly repeated action, spontaneous or occurring on every stimulation. This may improve and subside under general training and occupation; it is worst in deficient children who are allowed to be idle and loafing. The habitually *open mouth* suggests obstruction in the nose and throat: adenoids and hypertrophic rhinitis are very common in cases of mental deficiency.

It has been shown that the brain may be trained by the use of exercises for the hand, and receives impressions from its movements: the hand may be observed as an index of brain-status, the faults of which may thus be seen and corrected. A healthy well-trained child when told to hold out his hands

in front responds by raising each arm to a level with the shoulder, horizontal and straight at the elbow, the arms being parallel to one another. *The hands* should balance straight at the wrist and knuckles, with the fingers and thumbs in the same plane; this is the normal attitude with good brain-activity in preparation for action under guidance. Assuming this position momentarily helps to put the brain under control, just as removing all slouching habits improves the child. With inertness or fatigue the wrist droops, the metacarpal bones become adducted or folded, while the thumb falls and the fingers are partially flexed; the elbows are apt to be somewhat bent, and the left hand held at a lower level than the right. In the nervous *neurotic child* the hand tends to balance in a different position: the wrist droops, the palm is contracted and looks narrow, the thumb is bent back, and each finger extended beyond the straight line at the knuckle-joint, thus producing a claw-like appearance which is frequently seen in children convalescent from chorea, in bad sleepers, and in those who suffer much from headaches. These children may also present twitching of the fingers, either vertically or laterally. Bad postures are frequently imitated in school from other pupils; asymmetrical balance of the head and spine, as well as lordosis, should therefore be avoided, while good postures both in sitting and standing are taught.

Response of the brain is seen in action following some stimulus or direction given to the child; when this action is in harmony with the direction the response is intelligent. In response dependent upon mental action in the brain, a period of inhibition of spontaneity—partial or complete—occurs, corresponding to interaction among the centres in attention or thinking. A mere act of imitation helps in training, but the repetition of a mode of expression associated with the direction received is not a very intelligent action, though it is as much as may be expected from a very young pupil. It is little more than a reflex brain-action without much interaction among the nerve-centres, calling into play the results of experience and education: such is mechanical or parrot-like memory. For this reason a prompt response is sometimes of less value than a little delay in reply, if this indicates thoughtfulness. Accuracy in action, readily corresponding to the direction given, is of greater value than correct verbal expression or promptness and quickness: response in correct language is not to be looked for till a full vocabulary and the accurate use of terms have been gained by teaching. In mental arithmetic, when the pupil is told to add the numbers mentioned, and gives the correct answer, it does not much matter if his hands twitch and his eyes move about, while the feet shuffle, owing to some spreading or 'overflow' brain-action. When a sum in addition is worked out on paper, sight and eye-movements direct the brain-processes, while the fingers express the result; here irregular eye-movements and twitching fingers may lead to incorrect addition and mistakes in writing.

Besides receiving aid in the evolution of the general characters of brain-action and in the correction of faults, the child must also be trained in good mental habits. Efficient and well-arranged teaching can do much to render the brain healthy and strong for work during adolescence, and may make it less liable to neurotic disturbances and to the spreading or extra action exhibited in excessive

emotion or in mental confusion, which are as wasteful of energy as attacks of passion, epilepsy, or hysteria.

Higher Education.—In training the power of observation and in teaching methods of procedure, it is all-important that the pupil should know what *to look at* and what *to look for*; but beyond this, the processes of observation must be implanted in methodical order. This is analogous to making the pupil learn the order of the cases and genders according to which a Latin adjective is declined, before he learns the terminations and forms of each respectively; such fixed methods of thinking save the pupil's time and much unnecessary mental labour. Each mode of brain-action, necessary to the kind of work undertaken, should have been previously trained by practice: thus, before teaching the study of comparison and description of form, size, and area (geometry), the pupil requires training in the use of sight, eye-movements, and muscular sense, as well as in mental procedure according to the directions given and retained from practice. The boy may look at the face of his master who is teaching history or language, but he must learn to turn his eyes to the blackboard or map during a lesson in Euclid or geography. In Latin the prefix and termination of the words must be separately seen; in doing sums on paper the lines of figures must be followed in their order.

Mental fatigue should be avoided till the brain has grown, and its natural spontaneity has been in part co-ordinated by training; but at about seven or eight years old the brain of a healthy well-grown child has acquired an average weight of about 46 drs. (Dr. Thurman), and can begin to bear some temporary fatigue from mental effort without harm resulting. The fatigue of the day should be completely removed by sleep at night, and periods of mental effort must be followed by ample intercurrent activity in other directions, and by times for rest. Dr. Clement Duker recommends the following hours for work per week and sleep per night:—

	Ages	Work	Sleep
Children . . .	7-8	12	12½
„	10-11	25	11
„	15-17	45	9
„	17-19	50	8½

Weariness may be due to many causes: diet and ventilation may be defective, leading to the circulation of impoverished or impure blood through the brain; excessive muscular exercise may exhaust nerve-energy; late hours may lead to morning inertness; spontaneous self-contained thinking and imagining, with habits of mental introspection, sometimes lead to exhaustion in unoccupied and lonesome children.

The signs of fatigue should be known and appreciated by the teacher. In addition to those previously mentioned affecting the face, the fingers twitch, the shoulders are shrugged, the feet shuffle, and chattering or whispering begins; the head is held less erect, and the hands in their balance may show lessened neuro-muscular strength, as explained earlier. Action and response become slow and inaccurate, the mental status being reduced to a more childish condition. The question put may be repeated in place of a reply; the pupil is less controllable, while attention is not easily co-ordinated. Fatigue is not necessarily

proportional to the amount of school-work accomplished; it is important to observe the general expression of brain-action, not only its special results in the class-occupations. In the child the impressions retained are less exact than in the adult, while spontaneity is more abundant and may interfere with any established order of thinking; but spontaneous thoughts arising in the brain add to fatigue. At an early stage in education there exist but few established modes of thinking ready to come into play in forming a mental conclusion; effective training by implanting series of impressions, ready for methodical employment, does much to lessen the chances of mental fatigue.

Mental hygiene and careful general training promote good education, guided by observation; they aid brain-growth and the evolution of mental faculty; but to these must be added some experience of the conditions of life and social environment. This is specially necessary for children in boarding schools and institutions, who may otherwise experience less of the varied circumstances of life than those living at home and attending day schools. Besides abstract knowledge the child must also learn his position among the circumstances of life, and his social relations to other persons. Experience will teach the need of self-protection, of preparation for labour in earning a living, of honesty and good manners, as well as the value of learning. Hence children need comradeship as well as the influence of adults; school-habits and discipline lead to some understanding of cause and effect in social and in intellectual living. Teaching, if explanatory by words only, gives but little experience that can be of use to the child till actual impressions have been felt. If the boy has felt the pain of scalding water he may readily understand that hot things hurt, whether it be the coals and lamp which are alight, or the teapot which does not look hot; and he may understand further that it is dangerous to play with matches. Experience with animals is useful: children find out that dogs can bite, but that they are friendly if kindly treated. It is experience that couples the thought in an act of judgment leading to acceptance or refusal; a choice must be made between two offers, or a decision as to some line of action, and this necessity helps to form character.

The principles of hygiene should have some place among other subjects of instruction, whether this be formally taught or not; experience in feeling pleasure and activity amid plenty of light and air is educational. The effects of light and feeding or of starvation and partial darkness on plants may easily be shown in the school-room and in the practice of daily attending to them.

In dealing with an individual child, or when advising as to methods of class-training, the physician will consider the constitution of each child in relation to organised education; there are great differences, as well as inequalities, in the physical and mental abilities of children. Space will not allow a detailed account to be given of the examination of children for the purposes of educational classification, but the following propositions summarise the results of the writer's inquiries among 100,000 school-children:

I. The main classes of defect among children include a larger proportion of boys than girls.

II. The main classes of defect are much associated in the groups of cases.

III. Children with developmental defects often present also abnormal nerve-signs, and are delicate and dull.

IV. Children with indications of brain-disorderliness—that is, abnormal nerve-signs—are often dull pupils.

V. Dull pupils are often delicate, with indications of brain-disorderliness.

VI. Girls with developmental defect, or with brain-disorderliness, are more apt to receive harm and less good from their environment than boys.

VII. The effects of good physical training in school are to diminish the number of cases with signs of brain-disorderliness, and the number of dull children.

Weak or nervous children need careful training and management, which must be adapted to the child's needs, but not necessarily in all particulars according to his inclinations, for physical weakness predisposes to habits of indolence and loafing, which are best removed by the spirit and method of school-life, both in play and work, under the stimulus of emulation. This process of trying to level the boy up to the average of his companions calls for careful consideration and consultation in the school, when it is determined 'to make the boy work and play.'

Medical officers have in recent years been appointed by most of the School Boards in large cities to look after questions concerning illness among the children, and to take part in the selection of pupils who come under the provisions of the Education Act (Defective and Epileptic Children) 1899, and also to advise as to the methods of their training.

Feeble-minded children may be recognised and certified by observation of the *abnormal nerve-signs* already referred to, and by mental tests, as well as by *defects in developmental growth*, which will now be briefly described. The cranium may be bossed on either side of the frontal bone and at the parietal centres; the forehead may be narrow and shallow or present a vertical ridge. The volume of the cranial interior and its ossification are of great significance; the normal circumference at seven years is 20–21 inches. The palate is defective if narrow laterally, too much arched, or angular in front—i.e. V-shaped, with the upper incisors prominent; a small mouth-opening often co-exists with adenoids and nasal obstructions. The nasal bones may remain ill-developed, broad, and flat; this may improve with growth. The external ears are frequently defective in boys—large, outstanding, coarse in texture, the antihelix absent and the helix ill-formed, presenting a cave-like ear. The features are often defectively developed; the face as a whole may be small and infantile, or large, round, flat, with small features rising from its plane; the palpebral fissures small, with the transverse axis sloping upwards and downwards or upwards; a small mouth is more frequent than a large one. The lower jaw may be prognathous, large and heavy, or too small in proportion to the cranium. Defectively developed children, especially girls, are often stunted in growth, delicate, and ill-nourished. The presence of several developmental defects, with want of the general characters of good brain-action, combined with abnormal nerve-signs and absence of mental ability, indicates the probability of the child being feeble-minded.

The conditions of *sight* and *hearing* and of the mouth and throat, as well as the general health, need to be investigated; a careful physical examina-

tion of the child said to be dull is necessary before giving a diagnosis and prognosis; the facts thus observed will suggest treatment and the best methods of commencing brain-training.

FRANCIS WARNER.

CHILL.—A sensation of coldness accompanied by shivering, experienced during the rise of temperature associated with the onset of acute specific fevers or other inflammatory diseases; also occurring in nervous individuals, and in attacks of *megrim* without any rise of temperature.

In popular language a 'chill' is employed to mean exposure to cold or wet, followed by some acute disorder. Thus a cold draught playing upon the face may be followed by facial paralysis, sore throat, or bronchitis; that is to say, cold applied locally may excite disease in the neighbourhood of its application or in distant organs. It is probable that a 'chill' may act in several ways: (1) it may cool the blood circulating in the skin, especially when the vessels fail to contract rapidly under its influence; and the cooled blood may be supplied to internal organs; (2) it may affect the nerve-endings in the skin and by reflex action interfere with the circulation in the associated viscera (*see PAIN IN VISCERAL DISEASE*); in both these ways it may diminish the resisting power of the tissues to injury, and enable micro-organisms to gain a footing; (3) exposure to cold may check the secretions of the skin, the mucous membrane, or other parts.

Disease of the nose, throat, larynx, lungs, and kidneys is frequently traced to a 'chill.' Moreover diarrhoea, dyspepsia, acute and chronic rheumatism, and many other disorders are often traceable to no other cause. In some instances, as in acute pneumonia, it seems certain that the effect of chill is limited to the lessening of the resisting power, the immediate cause of the disease being the multiplication of bacteria in the body, and the dissemination of their toxins in the tissues.

The 'chill' so often 'taken' by those returning from densely crowded resorts late at night is probably the complex resultant of many forces, including the inspiration of organisms from the vitiated air; the lowered resisting-power depending on the effect of fatigue, and of over-heated air surcharged with carbonic acid and organic matter; and the effect of the sudden change of temperature on the nerves and dilated vessels of the skin, before referred to. Individuals differ in their susceptibility to 'chill'; and in any given individual the susceptibility of each organ is by no means identical. Moreover this susceptibility of special organs may vary with the age of the individual, the season of the year, and many other conditions.

TREATMENT.—The susceptibility to 'chill' may be diminished by the wearing of woollen under-clothing, and the careful regulation of individual habits, such as the temperature of the morning bath, the ventilation of sitting-rooms, and other details. The curative treatment of the maladies ascribed to chill is described under their respective headings.

H. MONTAGUE MURRAY.

CHIN-COUGH.—A synonym for whooping cough. *See WHOOPING COUGH.*

CHLOASMA (χλόα, a green herb).—SYNON. : Liverspot; Fr. *Ephélide*; Ger. *Leberfleck*.

An indefinite term often applied to any pigmentary

discolouration of the skin of a yellowish-brown or liver-colour tint, occurring in blotches. Its synonym, *ephelis gravidarum*, indicates its occasional association with pregnancy. It is sometimes used as a synonym of *linea versicolor* to denote the pigmentation caused by the *microsporon furfur*. See PIGMENTARY DISEASES OF THE SKIN.

CHLORAL HYDRATE, Poisoning by.—

Poisoning by chloral hydrate is a very common occurrence, this medicament being frequently taken in fatal quantity by misadventure. There is reason to think that it is also largely used for suicidal purposes.

ANATOMICAL CHARACTERS.—There may be an entire absence of any characteristic appearances after death by chloral hydrate; and at most these consist in more or less modified signs of asphyxia—especially a dark colour of the blood, and pulmonary and cerebral hyperæmia.

SYMPTOMS.—The most striking symptom of poisoning by chloral hydrate is the rapid supervention of quiet sleep, at first simulating natural sleep. In this stage the patient can be easily roused, but he speedily drops off again. The pupils are contracted; the respirations are full, deep, and regular; the pulse is not much affected. This condition rapidly deepens into full coma. The respirations slacken; and the pulse is either weak and slow, or, more commonly, rapid and irregular. The temperature of the body is reduced; the muscular system is totally relaxed. The pupils now dilate; and with feeble, thready pulse, the anæsthesia and paralysis gradually end in death, preceded by lividity and collapse. Exceptionally, in fatal cases, burning pain in the mouth, fauces, and throat, and symptoms of gastritis have been observed. In one case of recovery the patient became idiotic. The urine contains an abundance of glycuronic acid.

DIAGNOSIS.—The history of the case, or the finding of a vessel containing the medicine, coupled with the symptoms, will usually set all doubts at rest. Otherwise the case may be mistaken for poisoning by opium or other narcotic, for carbolic-acid poisoning, or for cerebral congestion. The pupil is not so contracted as in opium-poisoning; and, as the coma deepens, the pupils dilate instead of undergoing further contraction. There is an absence of the olive-green or black urine so commonly noticed in carbolic-acid poisoning, and of the peculiar odour of the breath, and of stains about the mouth and lips.

PROGNOSIS.—This will depend upon the state in which the patient is found, and upon the length of time which has elapsed since the ingestion of the poison.

TREATMENT.—Evacuation of the stomach by the aid of the stomach-tube is the first step in the treatment of a case of poisoning by chloral hydrate. Emetics, unless given early, usually fail to excite vomiting. The patient must be persistently roused, if possible, as in opium-poisoning (see OPIUM, Poisoning by). It is of primary importance to see that the temperature of the body be kept up by warm applications. Stimulants may be freely given, and hot coffee injected into the rectum. Strychnine ($\frac{1}{16}$ gr.) should be injected subcutaneously. Inhalations of amyl nitrite, and artificial respiration are advisable.

CHLOROFORM, Use of.—See ANÆSTHETICS.

CHLOROSIS (χλωρός, green or sallow).—**SYNON.**: Green-sickness; Fr. *La chlorose*; Ger. *Chlorose*; *Bleichsucht*.

DEFINITION.—A variety of anæmia occurring in a peculiar diathesis or habit of body, characterised by defective formation of the blood and vascular system.

ÆTIOLOGY.—Chlorosis occurs most commonly in young women from the age of puberty to twenty-one, but it may appear or reappear up to the thirtieth year; it is found occasionally in children and older women; it is very rare in men. It is believed to be more common in the higher ranks of life. Beyond these predisposing causes, the origin of the disease lies in peculiar characters of the blood and blood-vessels, to be presently described, which are believed to be congenital, and perhaps hereditary. In such subjects, and under the preceding circumstances, any of the numerous causes of anæmia may be sufficient to excite the appearance of chlorotic symptoms; but those which do so most commonly are bodily growth and development, the establishment of menstruation, disturbances of alimentation—particularly constipation, and an insufficient enjoyment of air, light, and wholesome muscular exercise.

ANATOMICAL AND CHEMICAL CHARACTERS.—The blood in chlorosis presents one strictly essential imperfection. The individual red corpuscle contains less than the normal amount of hæmoglobin, although the total amount of hæmoglobin in the blood in all probability does not fall below normal. The total quantity of blood is much increased (Lorrain Smith), and its specific gravity is much reduced. Both red and white corpuscles are sometimes deficient in numbers, and that proportionately. The liquor sanguinis is unchanged.

With this condition of blood certain associated abnormalities of the aorta and arterial system generally have been described by Virchow. The most striking of these is a hypoplasia or dwarfed condition of the aorta, represented by small calibre, increased elasticity, anomalous origin of the branches, and unequal thickness and fatty degeneration of the intima. The heart is, as a rule, small in early life, but full-sized or even hypertrophied at a later period, with traces of endocarditis. The condition of the ovaries and uterus varies extremely. In some cases the generative organs are described as 'infantile,' while in others they are either immoderately developed, or perfectly normal in every respect. The subcutaneous fat is often abundant; and the viscera present various degrees of fatty change. When the cardio-vascular changes are marked and advanced, there may be extensive secondary disease throughout the body.

SYMPTOMS.—The symptoms of simple chlorosis are those of mild anæmia, with certain important differences which become fewer and less marked, and finally disappear as chlorosis advances to the more serious disease. The present article will be devoted to a description and discussion of them; an account of the symptoms of anæmia will be found under its proper heading.

The appearance of the chlorotic girl is peculiar, inasmuch as the pallor of her complexion is accompanied by natural or even increased fulness, from the excess of subcutaneous fat. In blondes the

CHLORAL-HYDRATE HABIT.—See HABITS.

transparency of the skin is increased; in brunettes it is diminished, and a dull yellowish-grey colour of skin is the result, which, in contrast with the greyish-blue of the eyelids, may appear of a sickly green.

The patient's usual complaint is of this alteration of colour, menstrual disorder, debility, great breathlessness, cardiac symptoms, and various pains. She probably believes that she has heart-disease; her mother fears that she is consumptive. The symptoms and the cardiac and vascular signs closely resemble those of anæmia. But there is this important difference in the phenomena connected with the heart: that in many cases of chlorosis they indicate enlargement. Venous or arterial thrombosis may occur in the limbs and brain. The alimentary system is usually deranged, constipation often being an urgent symptom. The urine is abundant, watery, and pale. There is no dropsy in simple uncomplicated chlorosis. Rheumatic symptoms are occasionally associated. Pyrexia (99° – 103° F.) has been observed in some instances.

The *chlorotic constitution or diathesis* may be recognised by the following characters, which are variously associated in different cases:—Diminutive stature; imperfect sexual development; a history of peculiar anæmia in childhood, of anæmia with menstrual irregularity at puberty, and of previous attacks of symptoms of chlorosis; evidence of cardiac enlargement or mitral disease in the absence of all the ordinary causes of these; the occurrence of endocarditis during pregnancy or *post partum*; and the presence of any of the diseases which will be referred to under the heading of Complications.

COURSE, DURATION, AND TERMINATIONS.—The commencement of chlorosis is generally gradual. If neglected it tends to develop into confirmed anæmia. It is for this reason that pure chlorosis is a rare disease, while anæmia associated with the chlorotic diathesis is comparatively common. The duration of chlorosis is variable. It may reappear, and that more than once; but it is unlikely to return after the age of thirty, especially in the married woman. Death from chlorosis directly is excessively rare, but it may occur rapidly from cerebral thrombosis.

COMPLICATIONS AND SEQUELÆ.—According to Virchow, serious valvular disease and cardiac enlargement may be traced in some of the worst cases of chlorosis to the associated vascular condition; and the mitral valve is peculiarly liable to be attacked by endocarditis in rheumatic, puerperal, or septic fever. Hemorrhages, gastric ulcer, and exophthalmic goitre are believed to occur with comparative frequency in persons of the chlorotic diathesis.

PATHOLOGY.—The deficiency of the individual red corpuscle in hæmoglobin, and the deficiency of the blood in red and white corpuscles, indicate an imperfect growth of the corpuscular elements of the blood. With this blood-state there is associated a hypoplastic or dwarfish condition of the blood-vessels. In the embryo the blood and blood-vessels are developed from the same elements, the former making its appearance within the cells which produce the latter. The view of the pathology of this disease, therefore, adopted by the writer is, that the anomaly of blood and the anomaly of vessels are to be considered as together an expression of some congenital defect of the blood-vascular system, leading to imperfect growth

both of blood and of vessels. Any individual possessing such a blood-vascular system labours under a peculiar diathesis, and is said to be a *chlorotic subject* or to possess the *chlorotic constitution or diathesis*. If the other systems of the body are full-sized (which is not always the case), the dwarfish condition of the arteries of the chlorotic subject and the scanty supply of hæmoglobin may have some difficulty in satisfying the ordinary demands for blood, and especially for oxygen. This difficulty of the blood-vascular system will become a breakdown when the processes of alimentation are deranged, or when the blood is wasted by the excessive demands of growth, development, or hæmorrhage. Such a result is most likely to happen at periods of extraordinary demand within the economy, of which the establishment of menstruation is the chief. The symptoms of uncomplicated chlorosis are due to deficiency of oxygen in the system, while the cardiac enlargement and valvular disease are directly referable to the vascular hypoplasia, that is, to the obstruction caused by the narrow calibre of the aorta. The connection between the blood-vascular condition and that of the generative organs is more complex. On the one hand, the chlorotic diathesis or actual chlorosis interferes with the development and activity of the ovaries and uterus; on the other hand, disorders of the sexual functions are occasionally exciting causes of aglobulism. Many other hypotheses have been advanced to account for chlorosis. Andrew Clark maintained that when the bowels are inadequately relieved ptomaines and leucomaines are produced within the intestine and absorbed into the blood, 'where they originate in girls of a nervous type of organisation those alterations of the constitution of the blood which constitute the true pathology of this anæmia.' Another suggestion is, that sulphuretted hydrogen generated in the bowels as a product of indigestion destroys the organic compounds of iron which go to form hæmoglobin. According to a third suggestion, substances containing animal gum, which are developed in excess within the alimentary canal of the girl or woman, being required for the after nourishment of the embryo, act injuriously on the hæmoglobin-molecule. Still another theory is, that, from a deficiency of hydrochloric acid in the system, iron enters the blood in forms which cannot be assimilated by the corpuscles. Lloyd Jones suggests that chlorosis is the exaggeration of the blood-change that has for its end the storage of nutrient materials for the fetus *in utero*.

DIAGNOSIS.—Chlorosis has chiefly to be distinguished from pernicious anæmia and leucocythæmia. *See* ANÆMIA, PERNICIOUS; LEUCOCYTHÆMIA.

PROGNOSIS.—A speedy cure may be assured in uncomplicated cases subjected to careful treatment, though the liability to recurrence and the possibility of fatal thrombosis must not be forgotten.

TREATMENT.—The administration of iron is invariably successful, provided that, at the same time, a free supply of sunlight be insisted on, the diet and digestion rationally controlled, and physiological rest of the blood and of the organs of circulation be assured. *See* ANÆMIA.

J. MITCHELL BRUCE.

CHOLÆMIA (χολή, bile; and αἷμα, blood). **DEFINITION.**—This term denotes that condition in which the blood contains some or all of the bile-

constituents which have been secreted by the hepatic cells, and subsequently reabsorbed, either directly by the capillaries or *via* the lymphatics. See JAUNDICE; and BLOOD, Morbid Conditions of.

CHOLAGOGUES (χολή, bile; and ἄγω, I move).—**DEFINITION.**—Substances which lessen the amount of bile in the blood.

ENUMERATION.—The principal cholagogues are Mercury and its preparations—especially Calomel and Blue Pill; Podophyllum and its resin; Dry Extract of Euonymus ('Euonymin'), Iridin; Ipecacuanha; Aloes; Rhubarb; Sodium Salicylate, Sodium Phosphate, Sodium Sulphate, and Ammonium Chloride.

ACTION AND USES.—The liver has a twofold action—it *forms* bile, which is poured into the duodenum; and it also *excretes* the bile which has been re-absorbed from the duodenum and carried back to the liver by the portal circulation. Much bile thus circulates continually between the liver and duodenum, while part is carried down the intestine with the feces, and its place supplied by newly formed bile. When the quantity circulating in this way is too great to be completely excreted by the liver, it enters the general circulation and produces symptoms of *biliousness*. These are removed by the so-called cholagogues, which probably act by stimulating the duodenum, and thus carrying the bile so far down the intestine as to interfere with re-absorption. Among the best cholagogues are the preparations of mercury, which, with the exception of the perchloride, do not increase the secreting power of the liver, nor augment the quantity of bile formed by it. Their utility is greatly increased by combination with a saline purgative, which still further clears out the intestine, and completely prevents any re-absorption of bile. Other cholagogues, such as podophyllum resin, rhubarb, and aloes, actually increase the secretion of bile by the liver. At the same time, they probably prevent its re-absorption, in a similar way to mercurials and salines.

CHOLERA, ASIATIC.—**SYNON.**: Epidemic, Spasmodic, or Malignant Cholera; Fr. *Choléra Asiatique*; Ger. *Asiatische Cholera*; Ital. *Colera Asiatico*; Hind. *Haijah*; Chin. *Ho-louan*.

DEFINITION.—Asiatic cholera is a specific disease, characterised by violent vomiting and purging, with rice-water evacuations, cramps, suppression of urine, prostration and collapse, tending to run a rapidly fatal course; followed, in favourable cases, by febrile reaction, which may be mild or excessive, simple or complicated. These phenomena resemble those caused by the products of the early decomposition of meat, fish, shell-fish, and certain mushrooms (see PTOMAINES).

ÆTIOLOGY.—The disease is caused by a toxin produced by a spirillum which, gaining access to the intestinal canal, undergoes rapid and enormous multiplication on and in the mucosa and is

discharged with the evacuations. These constitute the medium and means of infection, which takes place most commonly through soil, water, and food; or may be conveyed by clothing or dust; or carried by flies; or in ill-ventilated rooms by exhalations from the bodies of the sick and dead. The disease is spread by human agency, mostly along trade-routes by land, sometimes in ships. Alluvial soil, low level, heat, moisture, organic pollution of soil and water, crowding, and neglect of domestic and personal hygiene are the conditions under which the disease is most apt to prevail.

The more we study the early history of Asiatic cholera, the better shall we understand that every outburst of the disease which has occurred beyond the confines of India can be traced back through a series of cases to that country. The disease prefers, in its extension, land-routes to sea-routes, and localities are invaded by cholera in consequence of communication with places previously attacked, commencing with Lower India.

The evidence in favour of the communicability of cholera by means of water or food contaminated with cholera-dejecta is overwhelming.

The bacteriology of the disease is discussed in a special article. See CHOLERA, Bacteriology of.

ANATOMICAL CHARACTERS.—The external appearances of the bodies of those who have died of cholera include the mottled skin, shrunken and livid appearance of the limbs, and other features hereafter described as characteristic of the disease during the stage of collapse. The temperature of the body rises after death, and it remains warm for some time. Rigor mortis sets in speedily, and is sometimes accompanied with muscular contractions, which displace the limbs of the corpse.

After death in the stage of collapse the only alteration to be discovered in the tissues and the blood is to be accounted for by the rapid drain of water into the intestinal canal which has occurred during life. The mucous surface of the stomach and small intestines is injected and swollen, and sometimes covered in places with an aphthous pellicle. The epithelium is shed during life, and drops off from the mucous membrane in large patches within an hour and a half after death. Dr. Koch states that the cholera-bacillus in many cases is found between the epithelium and the basement-membrane, and also within the tubular glands; 'it also settles in large numbers on the surface of the villi of the intestines, and often had penetrated into their tissue, and in some instances had passed as far as the muscular layers of the intestine.' The epithelial cells lining the kidney-tubules, bladder, and other organs are found detached from the basement-membrane, but they, like the blood, do not contain the cholera-bacillus. In both cases the epithelial cells show signs of degeneration.

Abnormalities of a specific nature, especially with reference to the amount of blood contained in the right side of the heart and lungs, have been described by pathologists as being characteristic of Asiatic cholera; and in many instances after death from this disease, if the *post-mortem* examination is delayed for a few hours, the right side of the heart will be found full of blood, together with the pulmonary artery and its divisions, while the lungs are collapsed and bloodless. But there are numerous exceptions to this state of the heart and lungs, and the condition above described is not infrequently

due to *post-mortem* changes; for if the bodies of those who have died of cholera be examined immediately after death, the left side of the heart will often be found as full of viscid blood as the right side. A peculiar shrunken condition of the lungs exists, depending on the dry and empty state of the bronchi, which allows the elasticity of the organs to drive the air out of them more completely than usual after the chest is opened. On the other hand, when death has occurred during reaction, the smaller tubes are often found full of pus, and parts of the lungs may be oedematous, or even in a state of broncho-pneumonia. The tissues in the acute stages are dry, and the blood is inspissated. Dark or light clots are prone to form in the heart and large vessels. In the stage of reaction inflammatory and even necrotic lesions of the viscera are often seen.

SYMPTOMS.—Asiatic cholera is most virulent and deadly at the commencement of an epidemic, and then usually begins without premonitory symptoms. The patient feels well up to within a few hours of the attack, or, it may be, goes to bed and sleeps soundly through the night, and immediately on rising in the morning is seized with violent purging and vomiting. After the first outburst of the epidemic, as a rule, cholera commences with diarrhoea, the stools being copious and watery, followed by great prostration of strength, with a peculiar feeling of exhaustion at the pit of the stomach; the sick person suffers from nausea, but seldom from actual vomiting or pain at the outset of the attack. If judiciously treated, many patients recover from this, the *first*, or *invasion-stage* of cholera; but if neglected the tendency of the disease is to grow rapidly worse. The stools become very frequent, and resemble in appearance and consistency the water in which rice has been boiled. These liquid evacuations flow away from the sick person with a sense of relief rather than otherwise. But the patient now commences to vomit, first throwing up the contents of his stomach, and subsequently all the water he drinks, mixed with mucus and disintegrated epithelium. The fluid is ejected from his mouth with considerable force, and this adds to the increasing prostration which is one of the most urgent and marked features of the disease. The patient complains of intense thirst, and a burning heat at the pit of his stomach; he suffers also excruciating pain from cramps in the muscles of the extremities, occasionally also of the trunk; he is terribly restless; and his urgent cry is for water to quench his thirst, and that some one may rub his limbs, and thus relieve the muscular spasm. Although the temperature of the sick person's body falls below the normal standard, he complains of feeling hot, and throws off the bed-clothes in order that he may keep himself cool. The pulse is rapid and very weak; the respirations are hurried; and the patient's voice becomes husky. His countenance is pinched, and the integument of his body feels inelastic and doughy, while the skin of his hands and feet becomes wrinkled and purplish in colour. The duration of this, the *second*, or *evacuation-stage* of cholera, is uncertain. It may last for two or three hours only, or may continue for twelve or fifteen hours; but so long as the pulse can be felt at the wrist, there are still good hopes of the sick person's recovery. The weaker the pulse becomes, the nearer the patient is to the *third*, or *collapse-stage* of cholera, from which probably not more than thirty-five per cent. recover. The result, however, depends much on the condition of the

patient's heart. It is quite possible, although the cases must be rare, that a sudden outpouring of fluid into the intestinal canal has been sufficient to cause syncope and death in persons suffering from weak heart, before the liquid contents of the bowels have had time to be ejected through the mouth or anus (*cholera sicca*).

In the third stage of the disease the vomiting and purging continue, although in a mitigated form; and the skin is covered with clammy perspiration, especially if the cramps are still severe. We are now unable to feel the pulse at the wrist, the lividity of the extremities and surface of the body increases, the patient cannot speak above a low whisper, his breathing is very rapid, his eyeballs are deeply sunk in their sockets, and his features are marvellously changed within a few hours. The urine is suppressed. The surface-temperature of his body may fall as low as 94° F. The patient remains terribly restless, longing only for sleep, and that he may be supplied with water. His intellect is clear, but he seldom expresses any anxiety regarding worldly affairs, although fully conscious of the dangerous condition he is in; sleep, and a plentiful supply of drinking-water, are the sole desires of a person passing through the collapse-stage of cholera. This condition seldom lasts for more than twenty-four hours, and reaction either commences within that period, or the patient dies in collapse, or he passes on into the *tepid stage*, which in ninety-nine cases out of a hundred ends speedily in death. In the tepid stage of the disease the patient's body feels cold to the touch, but the temperature, as shown by the thermometer, begins to rise rapidly, sometimes marking 99° or 100° F., or even higher in the rectum. The purging and vomiting cease; and the patient lies in a semi-comatose state, his eyes half-open, the ocular conjunctiva being deeply congested, the cornea hazy, and the pupils fixed. The pulse can be felt at the wrist, but the respirations are very hurried, suppression of urine continues, the patient's body is bathed in a cold clammy perspiration, the skin becomes of a dusky red hue, and death too frequently closes the scene within a few hours. The condition in some cases resembles the typhoid state.

On the other hand, the sick person having been in the collapse stage of cholera some twenty-four hours (it may be a longer or shorter period), the temperature of his body may begin to rise, gradually creeping up to the normal standard; the respirations diminish in frequency; the pulse returns; the patient can sleep, and after some thirty-six hours may pass a little urine: in fact, the functions of animal life are slowly restored, and the sick person recovers his health. This desirable result, however, is not infrequently thwarted by various complications which arise during the stage of reaction. Of these events the following are the most important:—suppression of urine; gastritis and enteritis; pulmonary congestion; meningitis; sloughing of the cornea; abscesses over the body; the formation of coagula in the right side of the heart or pulmonary arteries; hæmorrhage from the bowels; and roseola choleraica. Variations in the intensity, symptoms, and complications of cholera have suggested a definition of different forms of the disease, but such divisions are artificial, and the multiplication of names serves no useful purpose.

DIAGNOSIS.—The question of the diagnosis of Asiatic cholera is discussed in the articles on

CHOLERAIC DIARRHŒA, and CHOLERA, Bacteriology of.

PROGNOSIS.—The means of forming a prognosis in cholera may best be gathered from the preceding account of the disease. Speaking generally, the prognosis depends largely upon the previous health and condition of the patient, the rapidity of development of the disease, the severity of the symptoms, and upon the period in the epidemic at which the case occurs—that is, according as the patient has been seized at the outbreak, at the height, or towards the end of an epidemic.

TREATMENT.—In the first stage of Asiatic cholera we should endeavour to stop the purging, and without doubt opium is the drug upon which we may with the greatest confidence rely for effecting this purpose. When practising in the endemic area of cholera, one of the writers was in the habit of carrying about pills containing one grain of opium and four of acetate of lead, so that, if called to see a patient suffering from the disease in its early stage, no time was lost in administering one of these pills suspended in water. Similar combinations of opium with astringents and anti-spasmodics enter into the composition of a great variety of cholera-pills and tinctures employed in India. The next thing done was to make a large mustard poultice, and apply it over the whole surface of the abdomen. The patient was ordered to remain in bed, the evacuations being received in a bed-pan, and he was allowed nothing in the shape of food or water; but he might suck as much ice as he felt inclined for.

If the patient was purged after the first pill, a second was given, followed by a third if the second was ineffectual. It often happened that the first or second pill, together with the mustard poultice, ice, and rest, sufficed to check the progress of the disease, and the patient recovered. Supposing this treatment did not succeed, or that on first seeing the patient he was found to have passed into the second stage of the disease, we should still prescribe the pill, as above directed, suspending it in water, because in the solid form it might be rejected entire, and under any circumstances it would take time to be dissolved by the fluid contained in the stomach; the mustard poultice also should be applied, and the sick person kept warm and in bed. Ice is invaluable in this stage of the disease, and unless a person has passed through an attack of cholera, it is impossible to realise the immense relief it affords. It should be given in small lumps, the sick person eating and swallowing as much as he chooses. He will frequently devour a pound or two of ice in the course of an hour, and he cannot take too much of it. In the treatment of cholera there can be no question as to the value of ice. The patient should be prohibited from drinking water or any other fluid beyond that which he gets from the ice. The practitioner must be firm on this point, turning a deaf ear to the entreaties of the sick man or his friends that he may be permitted to swallow even a small quantity of water; for if they once break through this rule, it will be impossible to limit the amount of liquid the patient may consume. If this treatment does not check the progress of the malady, we may prescribe three grains of acetate of lead and fifteen drops of diluted acetic acid in water every second hour, and fifteen drops of diluted sulphuric acid in water every alternate hour, so that the patient should take a draught, first of one mixture then of the other,

every hour. Five drops of spirit of camphor may be added to each dose of the medicine, but this drug requires care in its administration, and should seldom be continued beyond five or six doses of from five to ten drops each. Should the vomiting be very severe, in spite of the free administration of ice, a second mustard poultice should be applied over the abdomen; all medicine must then be omitted for an hour and a half, after which time twenty grains of calomel may be sprinkled on the patient's tongue, and he should be made to wash it down with a little iced water. The cramps are best relieved by hand-friction, and if very severe, ease may from time to time be given by allowing the patient to inhale some ether. Powdered ginger is used in India to aid friction of the clammy surface, which may in cases of profuse cold sweating be rubbed with a soft towel. Hot-water bottles should be applied to the soles of the patient's feet, and also to his legs and abdomen.

Should the disease have reached the collapse-stage, there is but little we can do for the patient. Ice must still be given, and, if the purging is frequent, the sulphuric-acid draught (but no opium) may be administered every hour; heat and friction may with advantage be applied to the surface of the body; and the patient may now be permitted to drink iced water in moderation, provided it does not increase the vomiting. Wine and stimulants, if given by the mouth, do harm in this stage of cholera; but, if the purging has abated, enemata of warm beef-tea and brandy may be administered by the rectum every third hour. The restoration from collapse which follows intravenous saline injections is marvellous; but in most cases the fluid escapes rapidly through the intestines and the patient relapses. For this reason Cox, of Shanghai, has proposed continuous injection until reaction has been fully established. This measure is still on trial. Injections of water have been made into the cellular tissue, bladder, and peritoneum, but without much, if any, advantage. Injection of sulphuric ether has also been tried with evident, but mostly temporary, success. When reaction comes on, we must guard against doing too much—it is very rare indeed to see a patient in this condition sink from exhaustion, but probably many lives are lost by endeavours erroneously made, under the idea of keeping up the patient's strength. Iced milk or arrowroot is all that should be allowed to be given by the mouth for some time after reaction has set in; but enemata such as those above mentioned, administered *per rectum* every five or six hours, or nutrient suppositories, are often beneficial, especially if the stomach remains irritable. Under these circumstances we not infrequently find that a small quantity of solid food is digested, when soup and liquids are rejected. In each case, however, the dictates of common sense and experience must guide the medical practitioner in his treatment of the sick person through the convalescent stage of the disease.

With reference to the treatment of suppression of urine after cholera, we should get the patient to drink about half a pint of water every second hour, so as to add fluid to his blood. Dry-cupping over the loins should be employed; and ten drops of the tincture of cantharides in water administered every hour, until a drachm of the drug has been given. It need hardly be remarked that suppression of urine after cholera is a most dangerous

complication, and there is very little that can be done to restore the suspended functions of the kidneys.

PREVENTIVE TREATMENT.—The prophylaxis of cholera includes precautions against attack of individuals, protection of communities, and avoidance of invasion. The best safeguards against the disease are the maintenance of a high standard of health and scrupulous personal and domestic cleanliness. Alcoholism, bodily fatigue, and mental worry are special predisponents, and anything which tends to upset digestion or derange the bowels must be rigorously shunned. The use of saline purgatives when cholera is about is dangerous. Haffkine's method of anti-choleraic inoculation confers protection for a time, and diminishes the risk of contracting the disease (*see* CHOLERA, Bacteriology of). As a person affected by the disease is undoubtedly capable of communicating it to others and serving as a nidus and centre of diffusion, he is obviously an object of concern; but seeing that the communication from the sick to the healthy is effected solely by means of the intestinal evacuations, the safety of the community is sufficiently ensured by dealing with these effectively, with a view to the destruction of the contagium which they contain. If this is done the patient need not be considered a subject of danger or dread, and need not be isolated or avoided.

Among persons predisposed to its influence, the infecting organisms of Asiatic cholera will manifest their effects on the system within five days of having been swallowed, but the germs of the disease do not always engender symptoms of virulent cholera. Nevertheless, in milder cases of the disease the evacuations passed by the patient may contain the microbes of cholera, and may therefore, under favourable conditions for its development, produce a deadly type of the malady. Consequently, the following remarks are applicable to instances of so-called *cholérine*, as well as to the severer forms of cholera. If the disease has appeared within a neighbourhood, a searching examination must be made into the condition and source of the local water-supply, not overlooking that of the milk, which is too often diluted with water before being sold. All surface- and doubtful wells or reservoirs (especially those in the proximity of drains and cesspools) should be immediately closed; and it is desirable that the drinking water, before being consumed, should be carefully filtered and boiled. All accumulations of house refuse and filth must be removed; and dirty places, both within and without, must be freely disinfected and cleansed. There is no necessity when the disease is prevalent for making any alteration in the usual diet; but in times of cholera we cannot too strongly insist on at once checking any tendency to diarrhoea, especially if it be of a watery nature.

If called to treat a case of Asiatic cholera, care should be taken that the rice-water stools, and the matters vomited, are disinfected by means of a solution of mercuric chloride or some other germicide, which should be poured over the bottom of the vessel into which the evacuations are received from the patient; and directly the dejecta are passed, an equal quantity of a solution of one part of carbolic acid to twenty of water should be added to them, and they must be immediately taken from the patient's room, and disposed of as

follows:—If the sewage of the locality is conveyed away by means of a constant water-supply, the disinfected cholera evacuation should be thrown at once into the sewer. Drains used for a purpose of this kind must, however, be constantly flushed with a mixture containing about an ounce of ferrous sulphate to a pint of water. But if the drainage of the place passes into a cesspool, the disinfected cholera-stools should be buried in a deep hole in the ground, removed from wells, and, if possible, from human habitations. It is a most dangerous practice, however carefully cholera-stools have been disinfected, to allow them access to a cesspool. The room in which the patient has been treated must be freely disinfected, and his bedding subsequently burnt. If the sick person should die, the corpse is at once to be placed in a coffin containing a mixture of lime, charcoal, and carbolic acid: in fact, the body should immediately be buried in a mixture of this kind, and the coffin with its contents committed to the grave, or, better, consumed by fire within twenty-four hours of the patient's death.

By far the most important preventive measures to be adopted against cholera are to provide a pure supply of drinking-water, good drainage, ventilation, and cleanliness; for these means, if rightly enforced, must prevent the cholera-germ from spreading among human beings. In India when cholera breaks out among troops or prisoners, the practice is to move them into cholera-camps, situated at a distance from the infected locality, and located where the disease is absent and rare. This measure has been attended with good results, and is applicable to individuals as well as communities.

The Vienna Cholera Conference has decided that quarantine is applicable to the circumstances of cholera; but this subject, together with the duties incumbent on sanitary and port authorities with reference to the preventive treatment of the disease, hardly falls within the scope of this article. *See* QUARANTINE.

C. N. MACNAMARA.
KENNETH MACLEOD.

CHOLERA, ASIATIC, Bacteriology of.—

The *Comma-Bacillus* of Koch, the *Spirillum* or *Vibrio Cholera Asiatica*, now regarded as the specific cause of Asiatic cholera, is a minute rod-shaped organism, each cell measuring about 1.2μ in length and 0.5 to 0.6μ in thickness. These rods are curved to a varying degree, some forming a small segment of a circle, others being semicircular, and others again united in pairs so as to form an S-shaped curve. The name 'comma-bacillus,' by no means a good one, as the organism bears little resemblance to a printer's comma, has been universally adopted. Under cultivation, longer filaments, more or less spirillar or cork-screw in form, develop. The cells are actively mobile and should possess a single terminal flagellum, though there is some variation in this respect: thus the Massowah cholera-spirillum is described as having two flagella at each end, and an Indian variety has been stated to be non-flagellated. The cholera-spirillum does not form spores, though in old cultures certain vacuoles or granules of formed material have been described as such, and the rods lose their regular shape, and swollen and distorted involution-forms occur. The organism can be readily stained with the aniline dyes, a weak solution of fuchsin being perhaps the best;

but it is decolourised by Gram's method. See BACTERIA: coloured plate.

It is aerobic and facultative anaerobic, and may be readily cultivated upon the ordinary laboratory media at a temperature of from 20° to 37° C. According to Percy Frankland, although it grows readily in an atmosphere of hydrogen it does not develop in one of carbonic acid gas. In gelatine plates at 22° C. the cholera-spirillum forms roundish colonies which have slightly irregular margins and an uneven surface. At an early stage (20 hours) the colonies on gelatine plates appear whitish and somewhat less transparent at the centre than at the margins; later (40 hours) they become finely granular with uneven margins and with a marginal band of fine radial markings. Slow liquefaction of the gelatine occurs, and in consequence after 24 hours the plate is pitted and appears to be covered with minute air-bubbles. In a gelatine-stab-culture a cream-coloured growth develops along the puncture with slow liquefaction commencing at the surface and spreading downwards; in 48 hours there is a goblet-shaped area of liquefaction the size of a pea just at the surface, and having the appearance of a large air-bubble. The rate of liquefaction of gelatine varies considerably with different strains; in old laboratory-stocks it may be extremely slow. As liquefaction proceeds the liquefied area first assumes a hemispherical and later an elongated finger-like shape, to the bottom of which the whitish flocculent masses of growth sink.

On agar-agar, the surface-growth is thick, moist, smooth, and cream-coloured, generally with crenated margins. In stab-sugar-agar the growth is mostly confined to the surface and upper portion of the puncture, and there is no production of gas. In broth there is a free growth, the broth becomes turbid with a slight deposit, and a delicate film on the surface. In peptone-water the organism develops rapidly, especially at the upper layers of the fluid, with the formation of a distinct surface-pellicle; growth being best when the medium contains 1 per cent. of salt (Durham's modification). On potato a thin brownish layer develops at 37° C. In milk the organism multiplies rapidly with curdling and the production of acid, as is also the case on glucose-agar. Two important chemical changes are brought about by the growth of the organism in suitable media, viz. the formation of indol, and the reduction of nitrates into nitrites. Peptone-water is by far the most suitable medium for cultivating the organism in order to demonstrate these changes. A 24-hour culture treated with a little pure hydrochloric or sulphuric acid gives a bright rose-red colour, the formation of which is explained as follows:—The organism during its growth has formed indol and has also reduced the traces of nitrate present in the culture-medium to the condition of nitrite, the addition of the acid liberates nitrous acid which combines with the indol to form a red-coloured compound, nitroso-indol. Many organisms during their growth produce indol, the commonest example being the colon-bacillus, but it is the exception for nitrates to be reduced; hence in employing this reaction as a test it is necessary to use a pure acid, i.e. one free from nitrous compounds; should these be present, common organisms such as the colon-bacillus might give the reaction.

The cholera-spirillum retains its vitality in cultures for many weeks; it is readily killed by heat, its thermal death-point according to Kitasato being

55° C. with an exposure of 10 minutes; weak solutions of the common antiseptics also destroy it. In ordinary moist soil it remains alive for from 4 to 8 weeks, but in dry soil and in peat it dries out in a few days. In sterilised distilled water it usually dies within about 24 hours, but the addition of a small amount of sodium chloride greatly increases its longevity, and in sterilised potable water it may survive for many months; in unsterilised potable water its survival is greatly influenced by the presence of salt and of other bacteria. In unsterilised sewage it may live for 2–4 weeks (Houston).

The nature of the chemical products elaborated by the cholera-spirillum is but little known. It produces a peptonising and also a diastatic ferment, and Brieger has isolated cadaverin, putrescin, and two other basic bodies; but we now know that, owing to the methods of isolation employed, these are not improbably artifacts. Pfeiffer believes that the poison is intracellular. Brieger and Fränkel isolated a toxalbumen, Gamaleia a ferment-like body, and Westbrook various proteoses and proteid-like substances from cultures of the cholera-spirillum. Lastly, Metschnikoff has obtained a toxin by cultivating in a salt peptone-gelatine medium.

Relation of the Cholera-Spirillum to the Disease.—The cholera-spirillum may be said to be constantly found in the intestinal contents and discharges in cases of true Asiatic cholera, reaching the maximum degree of abundance at the height of the disease, and then almost entirely replacing the common bacteria of the intestinal canal, so that it is present almost as a pure cultivation; it has not been found in the excreta of healthy individuals. The organism is not met with in the internal organs or blood, but is confined to the intestinal canal, where it may penetrate beneath the intestinal epithelium.

The lower animals do not suffer from any condition at all resembling cholera (chicken-cholera is an entirely different disease), and it has therefore been difficult to reproduce the disease experimentally by inoculating or by feeding with pure cultivations of the spirillum. Koch, however, by washing out the stomach of guinea-pigs with alkaline solutions and paralysing peristalsis by means of opium or morphine, previous to injecting the cultivations into the stomach, induced a condition closely resembling cholera. Metschnikoff also has found that young suckling rabbits suffer from a choleraic diarrhoea when fed with cultures. Cases of accidental infection of man through pure cultivations are also on record. Thus in 1884, a student who was attending Koch's course on cholera in Berlin became ill with a severe attack of cholera, although there was at that time no cholera in Germany. A similar case is reported by Metschnikoff; and Dr. Oergel, of Hamburg, while injecting a guinea-pig, accidentally infected himself and died from the effects. On the other hand, Klein and others have swallowed cultures with negative results. Metschnikoff ascribes the immunity of animals to intestinal cholera to the inhibitory action of the other intestinal bacteria upon the cholera-spirillum, and he believes that the immunity or susceptibility of man and animals to intestinal cholera is largely influenced by the microbial flora of the digestive tract. Undoubtedly, in man, digestive disturbances are an important predisposing cause to an attack. The acid gastric juice probably plays an important rôle. Thus Macfadyen found that when the spirilla were administered in water to a fasting animal, they

could be detected in the intestine, but when the vehicle was milk none could be found, the inference being that the acid gastric juice, secreted on the introduction of the milk, prevented their passage.

The Bacteriological Diagnosis of Cholera.—The bacteriological diagnosis of cholera is carried out as follows. Cover-glass specimens of the rice-like flakes present in the evacuations or intestinal contents are prepared, stained with Löffler's alkaline methylene-blue, washed, dried, and mounted. If, upon a microscopical examination, large numbers of curved rods lying parallel to each other in groups are detected, the diagnosis of Asiatic cholera may be made with certainty; this, however, only occurs in perhaps half the acute cases. If this fails cultivations must be prepared. Sets of gelatine plate-cultures should be made, using a loopful of the dejecta, or, better still, an emulsion of a rice-like flake; a set of agar-plates may also be prepared by smearing a rice-like flake over agar-films in Petri-dishes. The plates being incubated at 22° and 37° C. respectively, the colonies of the cholera-spirillum will be recognisable in the gelatine-plates in from 24 to 30 hours, and in the agar-plates in from 12 to 16 hours. Peptone-water cultures should also be prepared at the same time from the rice-like flakes, the peptone-water being preferably contained in small Erlenmeyer flasks and forming a shallow layer at the bottom. In from 8 to 12 hours the upper layers of the culture-fluid may be examined for the presence of spirilla and gelatine-plate cultures, and fresh peptone-water ones also made for subsequent examination. After this the peptone-water cultures may be tested for the cholera-red reaction by the addition of a little *pure* hydrochloric or sulphuric acid.

The blood-serum of cholera-patients produces an agglutination of the cholera-spirillum similar to that produced by typhoid-serum on the typhoid-bacillus, and this test may be employed for diagnosis. It is stated that this reaction may be obtained as early as the first day.

The bacteriological diagnosis of cholera has of recent years become somewhat complicated by the detection and isolation from the waters of the Seine, Marne, Elbe, Rhine, Danube, and Spree, of spirilla bearing a close resemblance to the cholera-spirillum, but differing from it in certain minor particulars. Considerable light has been thrown upon the relation of these spirilla to the cholera-spirillum by the Bordet-Durham (agglutination) test, and by Pfeiffer's specific reaction. In the latter a mixture of an emulsion of the organism with a small quantity of the serum of a highly immunised animal is injected into the peritoneal cavity of a healthy guinea-pig. Half an hour to one hour afterwards the peritoneal fluid is examined microscopically, and if the reaction be positive, the organisms will be found in all stages of degeneration, in which case, according to Pfeiffer, the organism is to be regarded as belonging to the same species as that employed for immunising the animal from which the 'test' blood-serum was obtained. These cholera-like spirilla are now generally regarded as being harmless varieties of the cholera-spirillum—descendants probably of a cholera-spirillum of some cholera-epidemic of bygone years. The variability of the cholera-spirillum is demonstrated by Klein's experiments.

Other spirilla.—Mention must be made of two other well-known spirilla, which bear a superficial resemblance to the cholera-spirillum, but which can

be easily distinguished from it. They are the spirillum of Finkler and Prior, and the *Spirillum Metschnikovi*. The former, obtained from the dejecta in certain cases of so-called cholera nostras, liquefies gelatine much more rapidly than the cholera-spirillum and only gives a feeble cholera-red reaction after 2-3 days' growth. The *Spirillum Metschnikovi*, obtained from the intestinal contents of poultry, also liquefies gelatine more rapidly than the cholera-spirillum, but, like the latter, gives the cholera-red reaction; it is very pathogenic to pigeons. A spirillum obtained from cheese (Deneke's spirillum) likewise liquefies gelatine rapidly and does not give the cholera-red reaction. Litmus-milk is decolourised by the cholera-spirillum owing to reduction, but not by the Finkler-Prior or Deneke spirillum (Cahen's test).

Preventive Inoculation against Cholera.—Various methods of producing immunity to cholera have been suggested, but that of Haffkine alone needs mention. The vaccines employed are two in number: the first or weak, and the second or strong. The first vaccine is prepared from ordinary laboratory-cultures of the cholera-spirillum—attenuated by growing on surface-agar at 38° C. in tubes through which a current of moist air is being continuously passed. The second or strong vaccine is prepared from cholera-cultures, the virulence of which has been artificially increased by growing in the peritoneal cavity of a series—generally about twenty—of guinea-pigs. The vaccine itself is made by emulsifying agar-cultures with some sterile broth and adding a small quantity of carbolic acid or lysol. The dose of vaccine is injected hypodermically, the second or strong vaccine being administered from 3 to 5 days after the first or weak one. The injections cause some malaise, headache, and slight fever, which pass off in two or three days. The results of the anti-cholera inoculations seem to be decidedly favourable. For example, in Calcutta, taking the same households during the same period of time, there were among 654 uninoculated, 71 deaths, a mortality of 10·86 per cent.; among 402 inoculated, 12 deaths, a mortality of 2·99 per cent., a reduction of mortality by 72·47 per cent.

Cholera Anti-Toxin.—Attempts have been made to prepare an anti-toxic serum for cholera, but without much success. Metschnikoff by means of his toxin (*vide ante*) has immunised goats, so that 1 c.c. of their serum would neutralise four times the lethal dose of the toxin. Using young rabbits and producing an intestinal cholera by feeding, experiments showed that of the rabbits treated with this anti-toxic serum 51 per cent. survived, while of the untreated only 19 per cent. recovered.

R. T. HEWLETT.

CHOLERA INFANTUM.—See DIARRHŒA.

CHOLERA NOSTRAS.—See CHOLERAIC DIARRHŒA.

CHOLERAIC DIARRHŒA.—SYNON.: Cholérine; Sporadic Cholera; Cholera Nostras; Infantile Cholera; Fr. *Choléra sporadique*; Ger. *Sporadische Cholera*.

DEFINITION.—An acute catarrhal affection of the mucous membrane of the stomach and small intestines, attended with vomiting and diarrhœa and considerable prostration.

ÆTIOLOGY.—The disease is caused by an organic poison, probably of microbic origin. It prevails

sporadically in single or small groups of cases and does not exhibit any tendency to travel or spread. This form of diarrhœa is especially liable to attack those living in unhealthy surroundings.

In a hot and moist climate like that of Lower Bengal, choleraic diarrhœa is an affection which we meet with at all seasons of the year, and it is especially prevalent among infants who are being reared on cow's milk, or on other kinds of food prone to undergo putrefaction. Among the fish-eating Hindoos we frequently see several members of the same family who have been seized with symptoms of choleraic diarrhœa, attributable to the patients having partaken of fish which was slightly tainted. In fact, there are few more certain sources of this form of diarrhœa than stale fish; and it is evident that, whatever the deleterious material may be which food of this description contains, the mere fact of keeping it in boiling water for some time does not destroy its poisonous properties.

It occasionally happens that cases of choleraic diarrhœa occur among people residing in malarious districts, the diarrhœa taking the place of the cold stage of a fit of ague; patients in these circumstances may be seized with all the symptoms of severe cholera, but they almost invariably recover from the attack.

SYMPTOMS.—Choleraic diarrhœa begins suddenly: that is, the patient, whether an infant or an adult, has probably up to the commencement of the attack been in good health; there are, in fact, seldom any premonitory symptoms. A *child* may perhaps look somewhat paler than usual, and has a dark ring under his eyes, but beyond this appears to be perfectly well. Shortly after taking food, the infant vomits up a quantity of uncoagulated milk, the evacuation not being curdled like that from an overloaded stomach, the gastric secretion no longer having the power of coagulating the casein of milk. Soon after vomiting, or it may be before, the child commences to pass from the bowels an acid greenish-yellow fluid, containing flakes and often lumps of undigested food. The patient becomes very thirsty, is restless, and evidently in considerable pain, crying and drawing his legs up towards the abdomen. If these symptoms continue, the evacuations become colourless, resembling in appearance the rice-water stools of Asiatic cholera. The temperature of the body falls, the face becomes of a dusky hue, the features are pinched and the eyeballs deeply sunk in their sockets. The fontanelles are depressed; the child is evidently terribly prostrated, his pulse can no longer be felt at the wrist, and his crying passes into a weak whimpering; he eagerly drinks water when offered him; and, as the exhaustion increases, convulsions supervene, and the child dies within a few days or even hours. On the other hand, the symptoms may abate at any stage of the disease, and the little patient gradually recover his health.

In the *adult* the symptoms of choleraic diarrhœa are much the same as those above detailed. There are seldom any premonitory symptoms, and the attack begins with nausea and vomiting, together with a sensation of exhaustion referable to the pit of the stomach; the vomiting is speedily followed, or it may be preceded, by purging; copious watery discharges are thus passed out of the body, and the larger and more rapid the evacuations the more they come to resemble the serum of the blood, which, in fact, drains into the intestinal canal and

passes away from the stomach and bowels. The patient naturally complains under the circumstances of intense thirst. He is very restless; and at the commencement of the attack suffers from colicky pains in the abdomen, and subsequently from spasms and cramps, which often seize the muscles of the extremities. The pulse becomes small and weak, the respirations are hurried, the voice feeble, and the countenance pale and shrunken. The urine is scanty or suppressed; and the temperature of the body falls one or two degrees below the normal standard. These symptoms, as a rule, gradually subside, the purging and vomiting cease, and the patient falls off to sleep, waking more or less exhausted in proportion to the severity of the attack, but he usually recovers his health rapidly.

DIAGNOSIS.—The discrimination of the various forms of cholera rests upon data which may be classed as clinical, epidemiological, and bacteriological. The clinical features of all forms present a very close resemblance; so that given a mild case of cholera Asiatica and a severe one of cholera nostras, it would be difficult if not impossible to establish a diagnosis by comparison of the phenomena presented by each. To the practitioner who has had experience of both diseases the faces of cholera Asiatica reveals special malignity which, when the induction is large, can hardly be mistaken. Inquiry regarding the circumstances of cases and outbreaks is a valuable aid to diagnosis. A history of having partaken of tainted food or mushrooms, and the limitation of seizures to those who have so partaken, are sure guides to the formation of an opinion. In mushroom-poisoning fragments of the material may be discovered in the vomit or stool. A knowledge that epidemic cholera is in the locality or neighbourhood causes suspicion to attach to even mild cases of diarrhœa. The case-mortality of the disease when it attacks numbers is a strong indication of its nature. For the bacteriological diagnosis see CHOLERA, Bacteriology of.

PROGNOSIS.—Although choleraic diarrhœa in its more severe forms resembles mild cases of Asiatic cholera, it is a comparatively harmless disease. Unless among young infants, or old and sickly people with weak hearts, no matter how threatening the symptoms may be, however great the collapse and depression of the patient may seem, a previously healthy adult seldom dies of choleraic diarrhœa.

TREATMENT.—In cases of simple cholera occurring in the child, the important point we must enforce in our treatment is that the affected part shall have rest. In practice, however, it is often difficult to persuade parents and nurses that an infant can exist uninjured for ten or fourteen hours on iced water; nevertheless, we must insist on a plan of this kind being carried out. The little patient will eagerly swallow cold water, either from a bottle or spoon, and the child may be allowed to take as much cold water as he requires, and to suck ice, which may be wrapped up in the corner of a handkerchief and put into his mouth. A poultice made of equal parts of mustard and flour, applied over the abdomen, is often very useful in this form of disease. With reference to drugs, should the treatment above indicated not relieve the symptoms, or should the vomiting be very constant, from two to four grains of calomel may be given, and repeated if necessary in an hour's time; however, if the diarrhœa is the more prominent symptom, calomel is not required, but a teaspoonful of castor oil should

be administered. After the bowels have been cleared out, if the serous discharge continues, we should order astringents, in the form of $\frac{1}{2}$ of a grain of acetate of lead every hour, or $\frac{1}{16}$ of a grain of nitrate of silver, until the purging subsides. Tannic acid in combination with diluted sulphuric acid and sugar is frequently a useful combination to administer to children in cases of this description. With reference to opium, much as we dislike prescribing it for infants, it may be necessary in cases of simple cholera; but it should hardly be given in a mixture to be administered from time to time by a nurse. Opium under these circumstances can only be admissible when given by the medical attendant himself, in doses of one, two, or three minims of laudanum in a little weak brandy and water, carefully watching its effects. If the drug causes the child to sleep for a few hours, it may act almost like a charm: the infant awakes comparatively well. But if the opium has no such effect, we may be tempted to repeat the dose, but can scarcely give it a third time, at any rate until some hours have elapsed since the administration of the second dose. The symptoms having subsided, the child's diet must be strictly attended to, a good healthy wet-nurse as a rule being an urgent necessity in the case of infants. Lime-water may with advantage be mixed with the child's food. The diet must be most carefully ordered. See DIARRHŒA.

With reference to the treatment of adults suffering from choleraic diarrhœa, we must bear in mind that, unless among old and debilitated persons, the patient will, as a rule, recover without medicine. If therefore called to prescribe for a case of this complaint, we may order fifteen minims of laudanum, or a drachm of the compound tincture of camphor in water, to be taken (supposing the patient is very sick) immediately after vomiting; half the above dose may be given at the expiration of one hour; and again after another hour, unless the symptoms have in the meantime subsided. A large mustard poultice should be applied over the abdomen, and the patient must be confined to bed, and kept on ice and iced water; he should not, however, be permitted to swallow too much liquid. If the vomiting be severe, a scruple of calomel may be given to an adult, or in the first instance an effervescent mixture with hydrocyanic acid may be employed to allay the sickness. On the other hand, should the diarrhœa be excessive, we may with advantage prescribe four grains of acetate of lead and ten drops of diluted acetic acid every second hour; or pills containing a drop of creasote, a quarter of a grain of nitrate of silver, a grain of camphor, and two grains of Dover's powder, to be repeated after each loose motion.

Among old and weakly persons, and also in the case of infants, it is often necessary to administer brandy and water from time to time, according to the state of the patient's pulse.

C. N. MACNAMARA.
KENNETH MACLEOD.

CHOLERINE.—A term applied to a class of cases which occur during the prevalence of cholera, in which the milder symptoms of the disease are present. It has also been used to designate the poison on which cholera is supposed to depend. See CHOLERA, ASIATIC; and CHOLERAIC DIARRHŒA.

CHOLESTEATOMA (χολή, bile; and στεάτωμα, [Galen], a fatty tumour).—An encysted tumour, consisting chiefly of cholesterin. See CYSTS.

CHOLESTERIN (χολή, bile; and στερεός, solid). The term *cholesterin* occasionally used is derived from χολή, bile; and στέαρ, suet).—SYNON.: Fr. *Cholestérine*; Ger. *Cholesterin*; Gallenfett.

CHEMICAL AND PHYSICAL CHARACTERS.—Cholesterin is a mon-atomic alcohol represented by the formula $C_{27}H_{45}OH$ ($C_{26}H_{43}OH$ is also used). It exists under more than one isomeric condition. When pure it occurs as white, tasteless, inodorous, glittering scales which form needles when crystallised out from solution in chloroform, and as rhombic plates when derived from alcoholic and ethereal solutions. These plates are often deficient at one corner, are not infrequently imbricated, and their angles measure $79^{\circ} 30'$ and $100^{\circ} 70'$. Cholesterin is insoluble in water, alkalis, and dilute acids, but readily dissolves in ether, chloroform, boiling alcohol, benzol, turpentine, and solutions of the bile-acids, and its solutions are lævo-rotatory. It melts at $145^{\circ} F$. The crystals heated with strong sulphuric acid give a carmine-red colour, or with strong nitric acid a yellow colour. When treated with iodine and sulphuric acid a play of colours, red, blue, green, is produced. When dissolved in chloroform and an equal bulk of sulphuric acid added, it gives a red colour changing to purple with green fluorescence of the subjacent acid. A more delicate test consists in dissolving in 2 c.c. of chloroform, adding ten drops of acetic anhydride, and then H_2SO_4 drop by drop, the resulting colours being red, blue, green.

Cholesterin is present in most protoplasmic structures, and is apparently an essential constituent of all animal and vegetable cells. By some it is regarded as 'a cleavage product constantly formed in the metabolic changes of the living cell.' But the fact that it is found under conditions so widely different as normal nerve-tissue, blood-corpuscles, egg-yolk, bile, sebum, and numerous morbid products, is of itself sufficient to indicate the difficulty of stating precisely the why and wherefore of its existence. It must play some important part in tissue-formation and maintenance; its presence in the bile must be regarded as excretory and possibly due to the elimination by the liver of the products of the metabolism of nervous tissue; under pathological conditions it arises from a degeneration of the cells of inflammatory and other morbid products.

PATHOLOGICAL RELATIONS.—The pathological occurrence of cholesterin is varied and of unknown import. It is liable to be much increased in quantity in the normal places of its occurrence, e.g. in some instances of jaundice it is present in the blood in marked excess. In the bile it may be so abundant as to form crystals or be deposited as gall-stones, of which it forms the greater portion and occasionally the whole; under these circumstances the bile-salts and acids must be diminished in quantity (or the amount of cholesterin much in excess), so that these fluids can no longer hold it in solution, and hence it is deposited on foreign particles or on pre-existing concretions.

In the fæces, when they are free from bile, a considerable increase of cholesterin and fats may be met with. In exceptional cases of renal disease (as in lipuria, chronic nephritis; hydatids and

stone in the kidney) crystals have been deposited in the urine. The fluid of cysts, especially hydatid and ovarian, seems to be more liable to contain cholesterol than effusions into serous cavities. But sometimes it occurs in considerable quantities in hydrocele fluids, and it has been met with in old pleural and peritoneal effusions. Its presence in atheroma is well known. Occasionally it forms definite tumours, sometimes of no inconsiderable size, e.g. in kidney, broad ligament, brain, and elsewhere. Crystals of cholesterol have been detected in the sputum of tuberculosis and other pulmonary excreta and exudations of inflammatory origin.

CHOLURIA.—The presence of bile in the urine. See URINE, Morbid Conditions of; and JAUNDICE.

CHONDRODYSTROPHIA FÆTALIS.—See ACHONDROPLASIA.

CHORDEE (χορδή, a harpstring).—DEFINITION.—Painful imperfect erection of the penis during gonorrhœa. It occurs in slighter intensity in gouty and septic urethritis.

ÆTIOLOGY AND PATHOLOGY.—Chordee is most common in the second and third weeks of gonorrhœa. It rarely attacks the patient after the third week unless the inflammation has been re-kindled by alcohol or venery. In rare cases, chordee, absent in the acute stage, is violently developed after the primary inflammation has subsided. Erotic indiscretion is usually the cause. The bulbous portion of the urethra is generally intensely inflamed when chordee happens. It is uncommon when urethritis is strictly limited to the anterior or posterior portions of the canal. It invariably occurs when marked penile œdema and lymphangitis are present. The mechanism of chordee is probably as follows:—Inflammation from the surface of the urethral mucous membrane spreads deeply owing to invasion of its multitudinous ducts by micro-organisms. Inflammatory effusion around the adjacent erectile tissue of the corpus spongiosum ensues. An impeded vascular path results. With erection, the corpora cavernosa, being unaffected, distend and elongate normally, whereas the impaired corpus spongiosum does not. This causes the penis to assume an arched shape, the corpus spongiosum being tense and bowed. The sensory nerve-endings supplying the inflamed mucous membrane are thus pressed upon. Another explanation is that the inflammatory condition of the mucous membrane and sub-mucous tissue at the bulbous part excites reflex spasm of the muscles surrounding that part, thus cutting off the vascular supply to the corpus spongiosum by compression.

ÆTIOLOGY.—The causes of chordee are *indirect* or *direct*. The most common indirect cause is urethritis, urethral congestion, and irritating injections. Direct causes are the reflex irritants which usually produce erection during sleep, such as stimulating food and drink, strongly acid urine, excessive bed-warmth, a distended bladder or rectal scybala.

SYMPTOMS.—The organ grows suddenly turgid and assumes a bowed or crooked form, causing acute pain, which is felt at the part and towards the perinæum. In severe cases the strain causes

rupture of the mucous membrane and spongy tissue, with hæmorrhage. The loss of blood is usually limited to a few drops and gives relief to the pain. Rarely the hæmorrhage is free and prolonged.

TREATMENT.—Abstinence from stimulants of all kinds and late suppers, light clothing, and a hard mattress at night, are the best means of preventing chordee. Micturition whenever the patient wakes during the night must be enjoined. The urine should be rendered bland and alkaline and the erectile tendency combated. A mixture containing full doses of citrate of potassium, tincture of hyoscyamus, liquid extract of *Salix nigra* in decoction of *Triticum repens* should be given every sixth hour. At bedtime a pill containing two grains of camphor and one-third of a grain of extract of belladonna should be administered.

A suppository containing one quarter of a grain of morphine is useful, or the hypodermic injection into the perinæum of one sixth of a grain of acetate of morphine may be given. Both these applications should be followed by an aperient saline draught next morning. A nocturnal dose of twenty to twenty-five grains of chloral hydrate in syrup and water, repeated in four or six hours if needed, is trustworthy. Bathing the genitals and perinæum with very hot water for ten minutes before going to bed sometimes proves successful. The application of a spiral coil of narrow india-rubber tubing round the penis and scrotum, through which a continuous current of ice-cold water flows, is an excellent preventive. If rectal scybala be suspected as the exciting cause, the bowel should be cleared out at bedtime by means of a simple cold-water enema.

To subdue an attack of chordee the best measures are voiding urine; the application of cold to the perinæum, by sitting on a cold seat, or applying an evaporating lotion, or ice, and the upright posture.

CAMPBELL WILLIAMS.

CHOREA (χορεία, a dance).—SYNON.: Chorea Minor; St. Vitus's Dance; Fr. *Danse de St.-Guy*; *Chorle*; Ger. *Veitstanz*.

DEFINITION.—A disease of the nervous system, characterised by a succession of irregular, clonic, involuntary movements of limited range, occurring in almost all parts of the body.

The distinctive features of the movements are the entire absence of either rhythm or method in their recurrence; that not individual muscles but co-ordinate groups are affected; and not one or more groups only, but almost all the muscles in turn. There is not actual loss of command over the muscles, but voluntary movements are interfered with by superaddition of involuntary movements. As a rule the movements cease during sleep. There is frequently also muscular paresis varying in degree.

ÆTIOLOGY.—Chorea is a disease of childhood: it is most common between the ages of eight and twelve, very rare before six, and rare after sixteen. It is more than twice as frequent in girls as in boys, especially after the age of nine. It occurs more frequently in families in which nervous diseases are hereditary than in others. It is more common in large towns than in the country; and far more frequent among the poor than among those in comfortable circumstances. Want of proper food, neglect, ill-usage, constipation, with the anæmia induced by these means, are very common antecedents, or chorea may follow measles or other febrile disease of childhood. Children well nourished and

with a good colour, exposed to none of these causes, may however suffer. An intimate association between chorea and rheumatism has long been recognised. A large proportion of the children suffering from chorea have had acute or subacute rheumatism, and many will be found subsequently to develop symptoms of rheumatism if their history be followed up. Some of the most terrible cases met with, especially after the age of puberty, are those in which the chorea comes on during or just after acute rheumatism and is complicated by pericarditis. There is very frequently found in chorea a cardiac murmur, usually due to mitral incompetence. This may be the result of cardiac dilatation, in which case it will disappear on recovery. More often it is due to a valvular lesion caused by rheumatic endocarditis, either active or of older date. In most fatal cases of chorea which have been examined after death, the results of endocarditis or of pericarditis have been present. In adults, pregnancy divides with rheumatism the causation of this affection; recovery generally speedily follows delivery, and can rarely be brought about till this has taken place. Chorea may develop at any period of pregnancy, but most frequently commences in the third month. Bad habits, disorders of menstruation, intestinal worms, or other reflex sources of irritation, have appeared to set up the disease, but most commonly fright or some powerful emotion is assigned as the cause; and it is seldom that parents are not prepared with the instance required. Though, on cross-examination, frequently the history of the source of the fright is indefinite, or its date too distant to admit its causal relation, yet so many well-authenticated cases are on record of an attack of chorea following on a severe fright within a few hours to a few days, that we must regard fright or emotion as an important ætiological factor. Imitation has been assigned as a cause, but it is doubtful if true chorea can ever be attributed to this.

MORBID ANATOMY AND PATHOLOGY.—The study of chorea, as of epilepsy and many other affections of the nervous system, has been hampered by its being regarded as a morbid unity. The view here maintained is that it is a symptom rather than a disease, and that the characteristic movements are in relation not with the *nature* of the morbid change, but with its *seat*. Chorea has been called 'insanity of the muscles'; a better phrase (as one of the writers has said elsewhere) is 'delirium of the sensori-motor ganglia.' In delirium there is loss of control over the mental processes, with rapid succession of incoherent and imperfect ideas; in chorea loss of control over the motor apparatus, with movements excessive in point of number and extent, but wanting in vigour and precision.

In some cases of chorea nothing abnormal has been detected after death, but usually the minute methods of investigation now pursued yield positive results. Dr. Dickinson, in a paper read before the Royal Medico-Chirurgical Society of London in 1875, described dilatations of the minute arteries as existing throughout the brain and cord, more especially, however, in the corpus striatum and optic thalamus, with small hæmorrhages; and considered the disease to be due to a widely spread hyperæmia of the nerve-centres. Capillary embolisms with hyperæmia have been found by Tuckwell, Dana, and other observers, predominantly in the central ganglia, but also in the central con-

vulsions and spinal cord, accompanied by patches of softening and minute hæmorrhages. Swelling and hyaline degeneration of the pyramidal cells of the cortex and of the cells of the central ganglia have been described by different writers. Elischer found peculiar concentric refractile bodies, which have been termed 'chorea corpuscles,' in the perivascular sheaths of the vessels of the corpus striatum and internal capsule, but they have also been found in persons who have never had chorea. Conflicting results have been obtained in bacteriological investigations.

The *post-mortem* appearances consequently are indefinite and do not indicate any localisation of the morbid change. But it is to be remembered that the fatal cases are those in which there is not only extreme violence in the choreic movements, but usually also delirium and other symptoms. There are in fact multiple symptoms, just as there are multiple lesions, and we are called upon to distribute the symptoms, and assign them to their respective sources, by such knowledge of the functions of the different nerve-centres as physiology affords us.

The seat of the disease.—There is conclusive evidence that the seat of the disease is in the brain and not in the spinal cord. The arguments in favour of this are: (1) that *tonic* and not *clonic* spasm is characteristic of persistent spinal irritation; (2) the degree of control over the movements retained by the will; (3) their increase under emotion; (4) their cessation during sleep; (5) diminished reflex action; (6) the phenomena of hemichorea and its relations with hemiplegia. The evidence afforded by hemichorea is so conclusive that other considerations are of minor importance. The parallelism between hemichorea and hemiplegia is so perfect as to suggest at once that the two affections represent different conditions of the same nerve-centres, and is made more complete by the very discrepancies, as they may at first sight appear, which have been considered to be objections. In hemiplegia there are certain muscles which more or less completely escape paralysis: the *motores oculorum*, *orbiculares palpebrarum*, and other facial muscles, the muscles of the neck, chest, back, and abdomen. In hemichorea the irregular movements cross the median line and invade the opposite side in these same muscles. This has been explained by the hypothesis that since all these muscles act in compulsory concert with the corresponding muscles of the opposite side, the nerve-nuclei of the bilaterally associated muscles will be commissurally associated in the cord, so as to become in effect a single nucleus. This single nucleus for muscles on each side of the body, being connected with both hemispheres, is thrown into action by the sound hemisphere when its fellow of the opposite side is damaged, as in hemiplegia, thus preventing paralysis; and, on the other hand, is reached by the irregular impulses from the side of the brain affected in hemichorea, thus causing bilateral chorea in the parts enumerated.

In addition to the correspondence between hemichorea and hemiplegia just described, there are transitions from one to the other, and combinations of the two to be mentioned below. Hemiplegia may be succeeded by hemichorea (the *post-hemiplegic chorea* of various observers), although the movements are not strictly analogous; or chorea may be followed by paresis; or, as in a case reported by one of the writers, there may be with chorea of the

limbs on one side, first chorea, then paralysis (hemiplegiform), and then again chorea of the same side of the face.

The explanation of the phenomenon of post-hemiplegic chorea generally given is, that it is due to irritation of the motor fibres in the internal capsule by the lesion which originally caused the hemiplegia. But the most common site of the lesion in such cases is in or adjoining the optic thalamus, implicating, it may be, the sensory fibres in the posterior third of the internal capsule or the caudate and lenticular nuclei as well. In tumours also of the optic thalamus there are frequently choreic or ataxic movements of the limbs on the opposite side of the body. It is conceivable therefore that in both instances these irregular movements may be a reflex response to irritation of the cells in the optic thalamus, and that chorea may have an analogous origin. The character of the movements in the two diseases is, however, very dissimilar, and though it is a tempting theory to regard the optic thalamus and corpus striatum as a compound sensori-motor nucleus for complex co-ordinated movements and as the seat of the lesion in chorea, this hypothesis cannot be maintained in the present state of our knowledge of the functions of the basal ganglia.

Much is to be said in favour of the view of Sir William Gowers that the seat of the disease is in the motor cells of the cortex. Impairment of nutrition and functional disorder of these cells might produce the irregular movements, and a further degree of impairment of their functional activity, the paresis of chorea. The unilateral distribution of chorea which is common, and its subsequent extension to the other side, has its counterpart in epilepsy which is attributed to the spread of discharge from the motor cortex on one side to that on the other. The mental changes also that may occur in chorea point to impairment of function of the cortex.

The balance of evidence therefore is in favour of the seat of the disease being in the cerebral cortex, though in the absence of any definite characteristic lesion all views as to the pathogeny of chorea must be purely speculative.

The question which now remains to be considered is the cause of the derangement of function of the nerve-cells, affected in chorea. The frequent association of endocarditis with chorea in fatal cases gave rise to the well-known embolic theory advocated by Kirkes and ably maintained by Hughlings Jackson, that chorea is due to shreds of fibrin dislodged from the affected valves and obstructing capillaries in the brain. But the fact that in a large proportion of cases of chorea which recover there is no evidence at any time of endocarditis, and that in some fatal cases none is found *post mortem*, prove that this, if it be a cause of chorea, cannot be the only one.

So intimate is the connection between chorea and rheumatism that for the most part we must look on chorea as a manifestation of the rheumatic diathesis. That cases occur in which no history or evidence of rheumatism can be obtained is indisputable, but not infrequently articular or cardiac manifestations of rheumatism declare themselves at a subsequent period, and careful observation during an attack of chorea will often detect some dilatation of the heart, and it may be a soft mitral murmur which suggest inflammation of the myocardium of rheumatic origin. That chorea is a cerebral manifestation of rheu-

matism analogous to the articular and cardiac varieties is a plausible theory, and as the microbic origin of rheumatism is now conclusively established, it is possible that chorea is due to irritation of the motor cells in the cortex of the brain, by the organisms or their toxins.

Dr. Sturges ably maintained the view that chorea is a purely functional affection, and compared it with epilepsy. In favour of this view are the facts that an attack of chorea may be induced by fright or some emotion, or pregnancy, and that the disease is one usually limited to the period of childhood or early adolescence, a time when the nerve-cells are in an unstable and susceptible condition.

SYMPTOMS.—The disease usually begins with slight twitching of the face or spasmodic jerky movements of the hand. In a slight case the patient, usually a child, may be perfectly quiet when lying down, and for a short time even when sitting or standing, if not conscious of being under observation; but when walking, or while under examination, there will be various fidgety actions—abrupt flexion of the fingers, a sudden pronation of the forearm, or hitching up of one shoulder, or twist of the body, or there is shuffling of a foot on the floor, or, again, a jerk of the head or twitch of the mouth or eyes. If the patient be told to do anything, the movements will be multiplied and exaggerated in the muscles employed, and there is marked inco-ordination or voluntary movement. A small object will be picked up with difficulty, the hand being brought down upon it hastily and after various irregular excursions, and it may be dropped involuntarily. Sometimes, in the early stages, a child is punished for thus dropping an object and breaking it, or for fidgeting, before the nature of the disease is recognised. In a more severe case the grimaces, contortions, and jerks succeed each other without intermission. The gait is now very peculiar, being slow, shuffling, and uneven; the steps of irregular length and unequal time; and the line of progress deviating. In the worst forms of this disease every muscle appears to be thrown in turn into violent contraction, the face is distorted this way and that, the eyes roll to and fro, the teeth are snapped or ground together, the whole body writhes, and the limbs are in unceasing motion. It is to be remarked that, even in extreme cases, the movements, violent as they may be, are in some degree circumscribed; the arms, for example, are not thrown up over the head, nor do the legs go to the full extent of their range of motion; the tongue is rarely bitten, though the lips may be. Deglutition is greatly interfered with in a severe attack, and the evacuations may be discharged involuntarily. In the mildest forms the diaphragm and muscles of the chest and abdomen are affected, causing irregularity in respiration. The action of the heart may also be irregular, but this is probably secondary to the respiratory variations in frequency and depth, and is not attributable to chorea of the heart. Speech is very commonly more or less affected and occasionally completely lost for a time. The difficulty is usually articulatory, chorea of the muscles of respiration, phonation, and articulation interfering with utterance of words; but there is in some cases true aphasia, and when this is so, there is the same tendency to the association of aphasia with right hemichorea as with right hemiplegia. The intellect may suffer; the face has often an idiotic expression, usually

from the muscular contortion or atony, but sometimes indicative of temporary imbecility. In the violent and fatal forms there is almost always delirium. There is generally impairment of motor power: at times this amounts to complete paralysis, and the relations and combinations of chorea and paralysis, and especially of hemichorea and hemiplegia, throw much light on the disease. Paralytic chorea has been described as a special variety of the affection, but no line of demarcation exists between this and the common form. There may undoubtedly be impairment of sensation, though this is disputed by some observers. It is difficult to ascertain in all cases, but is most readily detected in hemichorea when the sound side can be employed for comparison; but in the violent forms of the disease, when the skin is gradually worn through by incessant friction, there is often so little complaint of pain that sensibility must, it would seem, be blunted. Reflex sensibility is also commonly dull.

It has already been stated that the movements cease during sleep; this is a rule to which exceptions are rare though not unknown, even in mild cases, and especially in hemichorea.

Chorea is usually gradual in access, even in the cases which ultimately become severe; it is very commonly one-sided for a time, and occasionally throughout, when the name hemichorea is given. It is not, however, strictly unilateral in these cases, as the movements transgress the median line and affect the corresponding muscles of both sides of the body at those parts where these are bilaterally associated, and where in hemiplegia there is immunity from the paralysis, as, for instance, the oculo-motor muscles, and the muscles of the neck, chest, and abdomen.

DURATION, TERMINATIONS, AND PROGNOSIS.—The average duration of chorea is about two months; if prolonged beyond three months it may be exceedingly chronic and go on, better and worse, for one or two years. There is a tendency to spontaneous recovery; but on the other hand relapses are common. Chorea is rarely fatal in children; when it is so, the case is usually acute and violent from a very early period of the attack, and is complicated by pericarditis or endocarditis: it is rare for a case to run the usual course for a time and then take on a very severe character. After puberty, and especially when it supervenes on acute rheumatism, it is often dangerous, and is usually serious when associated with pregnancy. See *INSANITY IN SPECIAL DISEASES*.

DIAGNOSIS.—It is scarcely necessary under this head to warn against the mistake of confounding with the movements of chorea the tremor or jactitation of disseminated sclerosis, which, though most common in adults, is not unknown in childhood. From 'spasmodic tic' chorea may be diagnosed by the limitation of the spasm to certain groups of muscles and by the sudden spasmodic character of the movements in the former disease. The rigidity and partial wasting of the limbs affected, with the rhythmical character of the movements and the history of the case in athetosis or post-hemiplegic chorea, will readily distinguish this affection from true chorea.

The diagnosis of paralytic chorea may be sometimes a matter of considerable difficulty, especially where the paresis is hemiplegic in distribution and no choreic movements are present. The paralysis is, however, never so complete as in hemiplegia due to organic disease, and frequently twitching

movements of the face are present when absent in the limbs. The onset of the paresis is usually gradual, and careful observation will after a time almost invariably detect twitching movements of the limbs or face when these are apparently absent at first.

TREATMENT.—In a large proportion of cases of chorea, especially such as come into the hospitals of London, rest and food, with perhaps aperients, are all that are required for recovery. But it can scarcely be denied that medicinal treatment often renders important services, especially in cases of a lingering character. The causation and pathological condition being various, it is to be expected that the remedies required will be different, and the attempt should be made to adapt the treatment to the special features of the case, the basis of all being the endeavour to improve the nutrition of the body generally, and of the nervous system, by good food, rest, and warmth. The food may be supplemented by cod-liver oil, and stimulants may be necessary in severe cases. Any recognised cause of reflex irritation should be removed, such as constipation or worms; irregularities or suspension of the catamenia should receive attention; when there is pregnancy it may perhaps be necessary to induce premature labour. Iron in some form is very generally useful, especially when the patient is anæmic. The drug that has been found most useful is arsenic, given in doses of three minims of the liquor arsenicalis three times a day, and gradually increased up to ten or even fifteen minim doses. Care must be taken not to continue it for too long, as neuritis or other symptoms of chronic arsenical poisoning may be induced. Trousseau sometimes gave strychnine in gradually increasing doses till its physiological effects manifested themselves. On the other hand, conium, recommended by Dr. John Harley, has been extensively employed; the only trustworthy preparation is the juice, which should be given in gradually increasing doses, beginning with a drachm and going up to one or two ounces if necessary, till its depressing effect on the muscles becomes evident. It has not, in the writers' hands, given satisfactory results. It is doubtful if any drugs are of great service, and the same may be said of the application of ether-spray along the spine. Baths, warm and cold, especially shower-baths, spinal douches, spinal ice-bags, and especially wet packs, may be useful in inducing sleep in severe cases.

In the terrible cases of acute chorea the great indications are to procure rest for the sufferer and keep up the strength. Milk, eggs, beef-tea, and other forms of concentrated fluid nourishment should be given freely, together with wine or brandy. Conium, hyoscyamus, cannabis indica, bromide of potassium or ammonium, and chloral hydrate, have been tried separately or in combination as sedatives, with more or less appearance of success, and chloroform has been administered. Chloral hydrate by the mouth or rectum, and hypodermic injection of morphine, with free administration of brandy, have, in the writer's judgment, appeared to be of most service as sedatives where the movements are very violent. It is in these cases that tartar emetic in full doses has been recommended; it is certainly tolerated in an astonishing degree. Restraint of the violent movements is often a great comfort to the patient: the limbs should be carefully bandaged with flannel and bound—the legs together, the arms to the sides, a folded blanket being placed across

the abdomen and hips, to keep down the body. If half-done it only adds to the suffering, but when properly carried out it gives a feeling of relief and favours sleep.

CHOREA, Electric.—**SYNON.** : Dubini's Disease.

The term 'Electric chorea' has been applied to a somewhat rare disease, met with in Northern Italy, which was first described by Dubini, an Italian physician. It is not related to true chorea, to which it appears to bear but a superficial resemblance. It is characterised by sudden spasmodic jerky movements of the extremities, the muscular contractions resembling those produced by electrical stimulation. Wasting of the muscles with paralysis of the limbs ensues and the disease usually proves fatal in a few months or, it may be, weeks.

It may occur at any age, and the onset is attended with pyrexia of varying degree and with pains in the back. The characteristic spasmodic movements are at first usually limited to one upper extremity, but gradually increase in intensity and spread to the leg on the same side, and then over the rest of the body. The limbs first affected then become feeble, the muscles waste and do not respond to faradism, and absolute paralysis succeeds, which may become general. Epileptiform seizures may occur, which sometimes prove fatal at an early period, or death may be postponed for several months.

The aetiology and pathology of the disease are at present unknown, but the clinical features suggest some acute infection or toxæmia which gives rise to organic change in the nerve-centres, apparently in the motor cells of the brain and spinal cord.

All treatment has hitherto proved unsuccessful.

CHOREA, Hereditary Progressive.—

SYNON. : Huntington's chorea.

This disease was first described by Dr. Waters, an American physician of Long Island, in 1842. In 1863 Dr. Lyon read a paper on the subject, and in 1872 Huntington gave a comprehensive description of the disease, which is therefore generally named after him.

The distinguishing features of the malady are (1) that it is hereditary; (2) that it is a disease of adult life, usually developing between the ages of thirty and forty, rarely before the age of twenty-five; (3) that it is progressive and incurable; (4) that it is accompanied by mental deterioration usually terminating in a condition of dementia.

ÆTIOLOGY.—The only known cause of this affection is its hereditary transmission from one generation to another. It is always hereditary, and frequently several members of the same family are affected. It is not associated with rheumatism, and no special exciting cause is known. Males and females are equally liable to the disease, and it does not occur till after puberty.

MORBID ANATOMY.—Thickening of the dura and pia mater, degenerative changes in the pyramidal cells of the cortex, atrophy of the cerebral convolutions, chronic diffuse encephalitis have been found by different observers, but there appears to be no characteristic or constant lesion.

SYMPTOMS.—The symptoms are both motor and mental. The former are the first to appear, and

consist of twitching or jerking movements of the face or limbs, resembling those of ordinary chorea, or rather, according to Dana, those of spasmodic tic. The movements are slight at the outset and can be controlled during voluntary action, but later on they become more violent and extensive, and quite beyond control. Every part of the body may be affected, so that speech and deglutition become difficult. The movements cease during sleep. Locomotion is peculiar when the disease is advanced: the patient sways from side to side, and walks with a high-stepping gait and jerky action of the feet.

The mental symptoms develop with the motor, usually commencing with gradual loss of memory and depression. There may be attacks of excitement or irritability, but the patient is usually apathetic and depressed, gradually passing into a state of dementia.

The average duration of the disease is ten to fifteen years, but some patients live for twenty or even thirty years from the onset of the disease.

No treatment is known which is able to arrest the course of the malady.

J. F. H. BROADBENT.

CHOROIDITIS.—Inflammation of the choroid. *See* EYE, AND ITS APPENDAGES, Diseases of.

CHROMIDROSIS (χρῶμα, colour; and ἰδρῶς, sweat).—Coloured perspiration. *See* SUDORIPAROUS GLANDS, Diseases of.

CHRONIC (χρόνος, time).—This word is applied to a disease when its progress is slow, and its duration prolonged.

CHVOSTEK'S SYMPTOM.—The term is applied to the increased mechanical excitability of the motor nerves and muscles of the affected parts, occurring in tetany. *See* TETANY.

CHYLOCELE.—The presence of milky fluid in the tunica vaginalis. *See* FILARIASIS.

CHYLURIA (χυλός, chyle; and ὄρον, urine).—**SYNON.** : Galacturia; Chylous urine; Fr. *Urine laiteuse*; Ger. *Chylurie*; *Milchsaftiger Harnabgang*. This term is applied to a state of the urine in which it presents the appearance of milk. The condition is caused by the admixture of chyle with the urine, and is generally due to the presence of the adult *Filaria sanguinis hominis* in the body. *See* FILARIASIS.

CICATRISATION.—*See* WOUNDS, Healing of.

CINCHONISM.—A condition induced by the administration of quinine, the chief active principle of cinchona. *See* QUINISM.

CIRCULAR INSANITY.—*See* FOLIE CIRCULAIRE.

CIRCULATION, Disorders of.—Abnormal excess and deficiency of blood are known as *hyperæmia* and *anæmia* respectively. Each of these may be *general* or *local*. We also recognise as a disorder of circulation stagnation or *local cyanosis*.

I. Hyperæmia.—*General* hyperæmia signifies excess of blood in the body, and is also called *plethora*. *Local* hyperæmia means excess of blood in a part. Such excess may be caused either by

superabundant supply, or by deficient removal of blood through the agency of the blood-vessels. Dilatation of the arteries, however produced, causes more copious afflux of blood, which fills the capillaries and veins in a corresponding degree, so that there is excess of blood in all the vessels of the part. This condition is called *arterial* or *active hyperæmia*, *active congestion*, or *determination of blood*. If, on the other hand, blood is imperfectly removed by the veins, these vessels, as well as the capillaries, become engorged, and the condition called *venous* or *passive hyperæmia*, or *venous congestion*, results. It is doubtful whether there can be *capillary hyperæmia*, except as the result of one of these conditions.

A. *Arterial or Active Hyperæmia*.—An excessive amount of blood can be conveyed by the arteries only under two conditions:—(1) Enlargement of these vessels by relaxation of their muscular walls; (2) Increased pressure within them, from obstruction of collateral channels with which they communicate, i.e. collateral hyperæmia.

(1) Relaxation of the muscular walls may be caused *directly* by violence or by warmth, as is illustrated in the redness of the skin produced by a blow, by friction, by heat, or by the reaction after intense cold. Sudden withdrawal of pressure has the same effect, as is sometimes seen on evacuating a hydrocele or fluid-collection in a serous cavity. Dry-cupping produces similar but more complex results, the veins being acted upon as much as the arteries. Relaxation of the muscle-fibres is produced also *indirectly* through the vaso-motor nerves. If these are paralysed, relaxation of the fibres occurs, and the arteries dilate. Experimental section of the cervical sympathetic in animals shows this most clearly; but the same result follows less constantly if other nerves containing vaso-motor fibres are divided or injured, such as the mixed nerves of the limbs, or branches of the trigeminus. Wounds of the brachial plexus have been found to cause hyperæmia of the fingers (*glossy fingers* of Paget). When the section is complete, hyperæmia is only transitory, and is soon followed by a return to the normal condition, or even by undue anæmia, which is permanent. In irritative lesions, on the other hand, such as gunshot wounds, hyperæmia continues as long as the irritation. In such cases it is possible that the lesion is not paralytic, but depends upon stimulation of the actively dilating vaso-motor fibres which physiologists have now shown to exist in many parts of the body, since stimulation of these produces the same result as paralysis of the inhibitory fibres. The hyperæmia of surfaces produced by friction or slight irritation has also been explained as a reflex action dependent on a stimulus conveyed by the sensory nerves to the medulla oblongata, and a resulting efferent current passing through the vaso-motor nerves to the peripheral vessels. But the same result may be produced when communication with the nerve-centres is entirely cut off. For instance, in a lesion of the fifth nerve causing complete anæsthesia in its cutaneous distribution, hyperæmia of the conjunctiva or skin may be produced by gentle friction. The action is therefore either a direct one on the vessels, or it is a reflex from sympathetic ganglia in the walls of the arteries. Hyperæmia often accompanies neuralgia, both depending upon some morbid condition of the nerve. The starting-point of the neurosis in all these cases may be, and often is, in

the central nervous system, and hence chronic diseases of the spinal cord or brain are often accompanied by general paralytic hyperæmia—that is, flushing, or by congestion of special parts. The same result may come from reflex nervous action, set up by disturbances of the digestive organs, the organs of generation, or of other parts.

(2) Collateral hyperæmia is a consequence of the rise of pressure produced by the blocking-up of arterial channels in the adjoining parts. It is usually effected by the enlargement of existing vessels. It occurs not only in the familiar instances of surgical ligature, and the sudden blocking of an artery by a plug (*see EMBOLISM*), but in the gradual obstruction which accompanies atrophic and sclerotic processes. When the chief efferent blood-channels to an organ become obstructed, its peripheral parts are very liable to become hyperæmic, as is seen in such cases as cirrhosis of the liver, granular kidney, and sclerosis of the brain.

SIGNS AND RESULTS.—The colour of parts in a state of active hyperæmia is, during life, bright red, the arteries, large and small, being visibly injected, while the capillaries, filled with arterial blood, produce a diffuse red colour. In experimental hyperæmia the blood may remain bright red even in the veins. The temperature of external parts becomes elevated, though not above that of internal parts. Sometimes there is obvious pulsation or throbbing. There may be swelling, which is due to simple enlargement of the vessels, not to exudation of fluid, since this does not occur from arterial hyperæmia alone. The nerves, both those of common sensation and those of special sense, are more excitable than they are normally. There is usually a subjective sensation of warmth, and there may be pain or itching.

Arterial hyperæmia may last for a long time without producing any change whatever in the part affected, but may, under conditions little understood, give rise to hypertrophy, which sometimes, though rarely, results from section of the cervical sympathetic. Transitory but repeated hyperæmic conditions more regularly produce this result, as in thickening of the skull from excessive exposure of the head to the sun; in hypertrophy of the skin of the face and its glands from frequently recurring hyperæmia (*acne rosacea*). This kind of hyperæmia constantly precedes inflammation, but can hardly be said to produce it. It does, however, render the tissues more vulnerable, bringing them into a condition in which a slight cause will set up inflammation. Unless the vessels are unsound, simple arterial hyperæmia does not lead to hemorrhage.

B. *Passive Hyperæmia or Venous Congestion*.—This may be due to (1) Feeble circulation; or (2) Obstruction in the veins.
